## 13 **Abstract**

14 The structure of the oceanic upper volcanic crust is less understood at slow-spreading  
15 ridges than at faster ones. Its construction is dominated by pillow lavas, reflecting lower  
16 effusion rates than those at fast spreading ridges, where sheet and lobate flows are  
17 common and flow off-axis while thickening the extrusive volcanic layer. Based on optical  
18 and high-resolution bathymetry data from the Lucky Strike segment (Mid-Atlantic  
19 Ridge), we document a mode of volcanic emplacement that likely operates at some  
20 magmatically robust slow- and ultra-slow spreading ridge segments, in the presence of  
21 strong gradients in magma supply. In these settings, sheet flows may efficiently transport  
22 melt away from magmatically robust segment centers in the along-axis direction, steered  
23 by normal faults, and exploiting along-axis topographic gradients, with limited across-  
24 axis flow. Surface lineations of sheet lava flows tend to be subparallel to fault scarps and  
25 the overall segment orientation, and show whorls, well-developed lava channels with  
26 associated levees, and surface fold structures at flow fronts. This mode of lava  
27 emplacement transitions away from the segment center to pillow-dominated seafloor  
28 near the segment ends, associated often with hummocks and axial volcanic ridges. This  
29 results in local lava emplacement due to a melt supply that is lower than at the segment  
30 center. We propose that fault-steering of lava flows along-axis, limiting off-axis transport  
31 as observed at fast-spreading systems, may be common at both slow- and ultra-slow  
32 spreading ridges with significant along-axis changes in magma supply linked to  
33 topographic gradients. As a result, the nature and properties of the extrusive volcanic

34 layer may vary significantly along axis owing to changes in the modes of volcanic  
35 emplacement, as transitions from sheet flows to pillow lavas may impact the porosity  
36 structure and hence the seismic properties of the extrusive layer in the oceanic upper  
37 crust.

38 **Keywords:** *Mid-ocean ridges; faulting; submarine volcanism; lava flows; morphology.*

### 39 **Highlights**

- 40 • Faults steer sheet flows over a few km along axis, impacting upper crust construction
- 41 • Along-axis changes in lava flow morphologies, evidence for melt supply gradients
- 42 • Different lava flow morphologies may affect seismic properties of Layer 2A

### 43 **1. Introduction**

44 Volcanic emplacement at the axis of mid-ocean ridges determines the nature, geometry  
45 and physical properties of the uppermost extrusive volcanic layer of the oceanic crust.  
46 Constraints on this structure have been obtained from geological observations (e.g.,  
47 submersible studies and ophiolites), and from drilling. At fast-spreading ridges, the  
48 volcanic layer is built through surface eruptions emanating from the axial summit trough,  
49 lava flows extending off-axis, in addition to dikes that do not reach the surface (Fornari,  
50 1986; Hooft et al., 1996; Soule et al., 2009). Slow-spreading ridges display a wide variety  
51 of volcanic morphologies resulting from varying melt supply both at the scale of  
52 individual ridge segments and regionally. Based on seafloor observations, it has been

53 suggested that pillow lavas are ubiquitous and often emanating from hummocks, small  
54 seamounts, or axial volcanic ridges, (Smith and Cann, 1992; Smith and Cann, 1993; Searle  
55 et al., 2010; Yeo et al., 2012; Estep et al., 2019), dominating upper crustal construction at  
56 slow spreading ridges (see also Figure S6 of Chen et al., 2021). Pillow lavas also suggest  
57 flow rates and lateral lava transport that are limited relative to sheeted lava flows (e.g.,  
58 Griffiths and Fink, 1992; Gregg and Fink, 1995). Sheet flows, which are common at fast  
59 spreading ridges, are scarce at slow- and ultra-slow spreading ridges (see Figure S6 in  
60 Chen et al., 2021), but they have been reported primarily at large seamounts or central  
61 volcanoes (Atwater; 1979; Gracia et al., 1998; Bideau et al., 1998; Bonatti and Harrison,  
62 1988; Edwards et al., 2001; Deschamps et al., 2007; Escartín et al., 2014; Asada et al., 2015),  
63 and therefore in areas where magma supply and hence eruption rates are likely elevated.  
64 These studies do not report neither the geometry nor the extent and direction of these  
65 sheet flows.

66 At fast spreading ridges, seismic Layer 2A, interpreted to represent the extrusive upper  
67 crust, is thinnest at the axis (~200 m) and thickens away from it (Kent et al., 1994; Hooft  
68 et al., 1996). At slow spreading ridges, seismic Layer 2A may be completely absent along  
69 magmatically-starved ridge sections, such as the South-West Indian Ridge (Sauter et al.,  
70 2013), or its thickness may exceed that of fast-spreading ridges, being up to 500 m thick  
71 or more at magmatically robust crustal sections (e.g., Hussenoeder et al., 2002; Seher et  
72 al., 2010c). Hence, the geometry, nature, and mode of emplacement of the extrusive upper

73 crust at slow-spreading ridge sections is both more variable and complex than that of  
74 fast-spreading ridges.

75 Seismic studies at on-axis Atlantic oceanic crust yield Layer 2A thicknesses that typically  
76 vary between 350-500 m (Hussenoeder et al., 2002; Peirce et al., 2007; Seher et al., 2010c)  
77 and may reach up to 850 m (Arnulf et al., 2014), with thicknesses up to ~1000 m off-axis  
78 (Estep et al., 2019). The overall seismic velocity of Layer 2A, as well as its vertical gradient,  
79 also show a temporal evolution attributed to hydrothermal alteration or clogging, pore  
80 geometry changes, among other factors (e.g., Wilkens et al., 1991; Grevemeyer et al., 1999;  
81 Estep et al., 2019). Layer 2A thickness variations of a few hundreds of m over spatial  
82 scales of ~10-20 km are also well-documented (e.g., Peirce et al., 2007; Seher et al., 2010c;  
83 Estep et al., 2019). At the Lucky Strike segment, Layer 2A thickness and upper crust  
84 velocity variations have been attributed primarily to a tectonically induced porosity  
85 reduction towards the segment ends (Crawford et al., 2010; Seher et al., 2010c), while in  
86 other studies and sites variations in seismic properties are attributed to alteration,  
87 volcanism, and to interactions among various processes (e.g., Christeson et al., 2019, and  
88 references therein).

89 The Lucky Strike segment is an ideal site to study links between volcanic style (e.g., sheet,  
90 lobate and pillow lava flows), and melt supply gradients along the segment, that may be  
91 linked to effusion rates (e.g., Griffiths and Fink, 1992; Gregg and Fink, 1995). We analyze  
92 high-resolution bathymetry and seafloor imagery, acquired with deep-sea vehicles over  
93 several cruises, to quantify the relative importance and along-axis variations of lava

94 morphologies, and document directions of surface lava transport, coupled to geophysical  
95 data available from the area (shipboard multibeam bathymetry, sonar, and prior seismic  
96 reflection studies). We propose a conceptual model of lava emplacement at magmatically  
97 robust slow-spreading ridge segments, that takes into account variations in eruption rate  
98 and lava transport along-axis. This model is fundamentally different from that proposed  
99 for fast-spreading ridges, and has consequences for both the overall structure of the upper  
100 volcanic layer, its physical properties (i.e., porosity and thus seismic Layer 2A structure),  
101 and its possible variations along-axis linked to melt supply changes that are common at  
102 magmatically robust slow-spreading ridge segments. The observations at Lucky Strike  
103 that we report here, likely apply to numerous magmatically robust slow- and ultra-slow  
104 spreading segments which show either elevated central areas, or central volcanos similar  
105 to those at Lucky Strike (e.g., Escartín et al., 2014). This is also supported by the  
106 observation of sheet flows at the center of several segments along the Mid-Atlantic Ridge  
107 (e.g., Atwater; 1979; Stakes et al., 1984; Gracia et al., 1998) and other slow-spreading  
108 ridges (e.g., Asada et al., 2015).

## 109 **2. Geological Setting**

110 The ~70 km long Lucky Strike ridge segment of the Mid-Atlantic Ridge (MAR) at  
111 ~37.25°N (Figure 1) is magmatically robust, and influenced by the nearby Azores hotspot  
112 to the Northeast (Cannat et al., 1999). Off axis, the older crust shows well-developed  
113 ridge-parallel, fault-bounded abyssal hills. At the segment center, a ~20 km diameter  
114 central volcano is underlain by a magma chamber at ~3 km depth beneath the seafloor

115 (Singh et al., 2006; Escartín et al., 2014), hosting at its summit one of the largest deep-sea  
116 hydrothermal fields along the MAR (Figure 2b *h* and *v*; Langmuir et al., 1997; Humphris  
117 et al., 2002; Ondréas et al., 2009; Barreyre et al., 2012; Escartín et al., 2014). The rift valley  
118 floor deepens along axis from ~1700 m depth at the central volcano summit, to >4000 m  
119 at the segment ends (nodal basins), while the axial valley transitions from a narrow, <2  
120 km wide rift zone that dissects the volcano summit (V1 and V2 in Figure 2b), to a broad  
121 valley floor at the segment ends. The rift valley lacks axial volcanic ridges in its shallowest  
122 section (Figure 2a and b), but these are common at distances >10 km from the segment  
123 center (Figure 2c and d, and south of *t* in 2b).

124 Previous geophysical studies along this segment provide bathymetry, gravity, seismic  
125 reflection and refraction data (Cannat et al., 1999; Singh et al., 2006; Seher et al., 2010a;  
126 Seher et al., 2010b; Seher et al., 2010c; Crawford et al., 2010; Combier et al., 2015).  
127 Geophysical data indicate that the crustal thickness is ~7-8 km at the segment center, and  
128 thins to <4 km at its ends (Detrick et al., 1995; Cannat et al., 2008; Crawford et al., 2010;  
129 Seher et al., 2010c), likely due to magma being focused to the segment center, and with  
130 reduced melt supply to the segment ends (Detrick et al., 1995). Fault patterns also change  
131 along-axis, while the rift widens and deepens towards the segment ends (e.g., Cannat et  
132 al., 1999; Escartín et al., 2014). Seismic data shows a clear Layer 2A/2B boundary at a two-  
133 way travel time of 0.4-0.5 s below seafloor (Singh et al., 2006; Seher et al., 2010c) and that  
134 corresponds to a thickness of >600 m (see discussion in Section 7.2).

### 135 **3. Data and surveys**

136 We benefit from data previously acquired at the Lucky Strike segment during several  
137 cruises over more than 20 years. Here we summarize the datasets used, while full  
138 information is provided both in the Supplementary Materials and in the references.  
139 Shipboard multibeam bathymetry data, gridded at 40 m and fully covering the ridge  
140 segment and adjacent crust, were acquired during the SISMOMAR  
141 (<https://doi.org/10.17600/5010040>) and SUDAÇORES  
142 (<https://doi.org/10.17600/98010080>) cruises (Figure 1a). High-resolution sidescan sonar  
143 data, covering the central part of the rift valley floor (Figure 1b), were acquired with the  
144 deep-towed WHOI DSL120 system during the Lustre'96 cruise (<http://www.marine-geo.org/tools/entry/KN145-19>). Sonar grids are publicly available (Data DOI:  
145 [10.1594/IEDA/321460](https://doi.org/10.1594/IEDA/321460)) and processing details are given in Escartín et al. (2014). Near-  
146 bottom multibeam bathymetry data (Figure 1b) were acquired during 3 cruises:  
147 MOMARETO 2006 (<https://doi.org/10.17600/6030130>), MOMAR'08-Leg 1  
148 (<https://doi.org/10.17600/8010140>) and BATHYLUCK'09  
149 (<https://doi.org/10.13155/47147>). Those surveys were conducted using both the  
150 remotely operated vehicle (ROV) VICTOR and the autonomous underwater vehicle  
151 (AUV) AsterX. The high-resolution bathymetry grids in Figure 1b are publicly available  
152 (<https://doi.org/10.17882/80574>).

154 Seafloor images were obtained from a) Vertical electronic still images acquired with the  
155 WHOI TowCam System (GRAVILUCK'06 cruise, <https://doi.org/10.17600/6010110>),  
156 along several profiles crossing the ridge axis and distributed along-axis; b) Submersible

157 Nautilie video images (Figure 1a; GRAVILUCK'06 cruise), primarily along the ridge axis;  
158 c) ROV VICTOR video imagery (Figure 1a; MOMAR2008 and BATHYLUCK'09 cruises,  
159 respectively <https://doi.org/10.17600/8010110> and <https://doi.org/10.17600/9030040>)  
160 both along the axis and in adjacent areas; and d) seafloor photomosaics over the Lucky  
161 Strike hydrothermal field (Figure 1a; Barreyre et al., 2012), derived from processed black-  
162 and-white vertical images acquired with ROV VICTOR (MOMAR2008 and  
163 Bathyluck'09), and publicly available (<https://doi.org/10.17882/77449>,  
164 <https://doi.org/10.17882/77405>). Photomosaics from ROV surveys (outlines shown in  
165 Figure 2a), and from individual camera tows, are also publicly available (see  
166 Supplementary materials for details).

#### 167 **4. Identifying volcanic features to constrain volcanic style**

168 To document and quantify the variations in volcanic style along-axis, we integrate the  
169 interpretation of both high-resolution bathymetry, and optical seafloor imagery (Figures  
170 1 to 4), that also cover a wide range of spatial scales (from ~1 km, Figures 2 and 3, to <1  
171 m, Figure 4). Bathymetry, coupled with available sonar imagery (see Escartín et al., 2014)  
172 is primarily used to identify volcanic structures at larger scales, such as the limits and  
173 structure of lava flows, volcanic ridges, collapse pits associated with fissures, in addition  
174 to faults and fissures that are pervasive in the area (Figure 2). Imagery is used to quantify  
175 the distribution and abundance of dominant volcanic style along camera tow transects  
176 and on photomosaics (Figures 1, 2 and 4). As seafloor optical imagery is also oriented and

177 scaled, we digitize the orientation of lava flow structures (e.g., lineations on lava flow  
178 surfaces) to determine the direction of lava flow transport in the study area.

179 The bathymetry shows a clear gradient in fine-scale seafloor morphology away from the  
180 Lucky Strike segment center. At and around the central Lucky Strike volcano, that shows  
181 summital volcanic cones (V1 and V2 in Figure 2), the smooth volcanic seafloor is faulted  
182 by a dense network of closely spaced normal faults that bound numerous horsts and  
183 grabens (Figure 2a and b). South of the volcanic cone V2 (Figure 2), this smooth volcanic  
184 seafloor transitions to hummocky seafloor, typical of slow-spreading ridges, at a distance  
185 of ~2.5 km in the along-axis direction (Figures 2 and 3; Escartín et al., 2014), with well-  
186 developed axial volcanic ridges further south (Figures 1 and 2). The seafloor relief also  
187 reveals the recent, mostly unfaulted along-axis lava flow (Figure 2).

188 Based on seafloor imagery, we identify and map systematically the distribution of  
189 different lava morphologies: sheet flows, lobate flows, and pillows throughout the study  
190 area (Figures 2, 3 and 4). In addition to quantifying along-axis variations in the mode of  
191 lava flow emplacement, we also a) document the structure of the most recent axial lava  
192 channels (Figures 2, 4a, 5), b) determine if the sheet flows are sedimented or  
193 unsedimented as a proxy of age, c) study the nature of collapse pits along fissures and  
194 grabens (Figure 2) and d) digitize lineations on the sheet flow surface to document the  
195 flow direction and the patterns of associated surface melt transport (Figure 6).

#### 196 *4.1 Along-axis lava flows and faulting*

197 The high-resolution bathymetry in Figures 2 and 3 reveals a young 3-km long sheet flow,  
198 which originated at the base of the unrifted southern volcanic cone V2 in Figure 2 at the  
199 summit of the central volcano. This lava flow is the youngest identified in the area, it is  
200 unfaulted, displays an acoustically reflective surface (Fig. 6 in Escartín et al., 2014), and  
201 seafloor observations show that it is visually fresh and unconsolidated lavas (Figure 4 a  
202 and b; Escartín et al. 2015). The across-flow profiles (Figure 5b) show a ~150 m wide  
203 channel near its source, with a central part that is lower at the center relative to its edges  
204 (1-4 m, p1 in Figure 5b). Distal parts of the flow show instead a domed structure, with a  
205 lava flow center higher by a few m (e.g., p2, p4, p6 in Fig. 5b) to >10 m (e.g., p5) with  
206 respect to the flow margins. This lava flow was clearly steered by normal fault scarps  
207 (Figure 3a and 5b) and exploited mild topographic gradients that increase from ~1.2° near  
208 the volcanic cone to ~5.2° further to the south (Figure 5).

209 The high-resolution bathymetry and seafloor imagery reveal older sheet flows both in the  
210 central area (Figures 3a and 4c) or emplaced in low areas among hummocks downrift  
211 from the segment center (Figures 2 and 3c). In all cases, the main flow direction appears  
212 to be along-axis, and steered by either axis-parallel faults or the flanks of hummocky  
213 ridges, which also tend to be elongated along-axis. These sheet flows show a folded  
214 surface morphology, with an amplitude of 1-2 m, and wavelengths of ~10-20 m in along-  
215 flow profiles (Figure 5c). Locally, these structures show evidence of flow off-axis instead  
216 of along-axis, that have breached laterally at fault terminations, or covered and flowed  
217 over faults (Figure 3). On camera tow imagery, older sheet flows can be identified when

218 lineations or whorls are apparent through the thin sediment veneer covering them  
219 (Figure 4c).

220 Near the young sheet flow source, the depressed flow center shows surface lineations  
221 and whorls, that vary in size from a few m to up to ~20 m in diameter (Figure 4a). Striated  
222 lava surfaces within lava flow channels are common along many ridge sections (e.g., East  
223 Pacific Rise; Chadwick et al., 1999) and their orientation indicate the lava flow direction.  
224 The lineations that we observe at Lucky Strike also seem to be reliable indicators of lava  
225 transport; they are visible in photomosaics over lava flows that are well constrained on  
226 the bathymetry (Figure 2a and 4), and their distribution could also be observed in detail  
227 during a submersible dive following this recent lava flow (see Figure 1a and 4b). These  
228 textures (Figure 4) document both high effusion rates and shearing of the lava flow  
229 surface during its emplacement (Ballard et al., 1979; Griffith and Fink, 1992; Gregg and  
230 Fink, 1995; Lonsdale, 1977). Flow margins that are raised relative to the flow center have  
231 hackly lavas that record the break-up of the lava surface at flow edges (Figure 4a;  
232 Chadwick et al., 1999; Soule et al., 2005). These volcanic facies are similar to those from  
233 lava channels at the EPR, that also show a depressed lava channel likely recording  
234 drainage downflow away from the axis during lava emplacement and subsequent  
235 deflation (e.g., Chadwick, 2003; Soule et al., 2005).

236 Recent lava flows erupted at Lucky Strike segment center have thus been efficiently  
237 steered along-axis by normal fault scarps, and also along the flanks of hummocky ridges,  
238 which are aligned along-axis, following gentle along-axis topographic gradients. Lava

239 flows can breach laterally and flow short distances off-axis, particularly in areas of low  
240 fault scarp relief (for example at  $\sim 37.27^\circ\text{N}$  in Figure 3a).

#### 241 *4.2 Lobate and pillow lavas*

242 Our imagery reveals that both lobate and pillow lavas (Figure 4 d and e) are present  
243 throughout the study area. Lobate lava morphology, which corresponds to local flow  
244 rates intermediate between those of sheet flows and pillow lavas (e.g., Griffiths and Fink,  
245 1992), are commonly found at the edges of sheet flows or preserved between branches of  
246 jumbled flow. Pillow lavas are found throughout, and particularly making up hummocks  
247 and axial volcanic ridges. In sloping areas, pillows are elongated, indicating the direction  
248 of lava transport downslope (Figure 4e). Both hummocks and axial volcanic ridges thus  
249 build up through pillow lava emplacement as observed elsewhere along the MAR (e.g.,  
250 Ballard et al., 1975; Yeo et al., 2012).

#### 251 *4.3 Grabens and collapses*

252 The high-resolution bathymetry also reveals faults and narrow grabens (10-50 m wide  
253 and up to 15-20 m deep), that are both parallel and oblique to the ridge axis (Figure 3).  
254 Collapse pits, with circular or elongated shapes are clearly aligned along some faults  
255 forming narrow grabens (Figure 3a and 4f), that are likely associated with dikes  
256 subseafloor subparallel to the ridge axis. Pit diameter is variable and ranges from a few  
257 m, to structures that are wider than 50 m, and with depths reaching  $\sim 20$  m. Imagery and  
258 high-resolution bathymetry data show that the edges of these pits lack both elevated rims

259 and debris, features expected for structures of an explosive origin (volcanic degassing or  
260 hydrothermal explosions). Instead, the morphology is consistent with local gravity  
261 collapse, and comparable collapse features associated with dike-induced grabens have  
262 been identified both in subaerial volcanic environments (e.g., Okubo and Martel, 1988)  
263 and at other planets albeit at much larger scales (e.g., Mege et al., 2003; Davey et al., 2012).  
264 Some pits are flat-bottomed, a structure that is consistent with possible lava infill linked  
265 to underlying diking along pitted fissures and grabens. Other pits show instead a concave  
266 morphology consistent with debris infill due to gravity collapse with no lava infill.

## 267 **5. Along-axis lava transport by sheet flows**

268 High-effusion rate submarine eruptions feed lava flows that follow topographic  
269 gradients, transporting lava downslope over distances of hundreds of m to a few km (e.g.,  
270 Gregg and Fornari, 1998). The flow front stops advancing either when lava effusion  
271 ceases at the source (volume-limited eruptions) or when lava is efficiently cooled, and the  
272 solidification of the crust stops the flow (cooling-limited eruption), as is the case at very  
273 short spatial scales (meters) for pillow lavas (e.g., Griffiths and Fink, 1992; Gregg and  
274 Fink, 1995; Gregg et al., 1998). Sheet flow lava morphology is thus indicative of relatively  
275 high eruption rates, significant eruptive volumes, or both (e.g., Griffiths and Fink, 1992;  
276 Gregg and Fink, 1995). This is consistent with the presence of lava whorls (Figure 4 a and  
277 c) and well-developed lava channels near the source of the young lava flow (Figures 3  
278 and 4) that emanates from the base of the volcanic cone (V2 in Figure 2) at the summit of  
279 the central volcano, and that shows incipient rifting (Escartín et al., 2015).

280 The most recent flows identified here flowed southwards (Figure 3), as shown by surface  
281 folding away from the lava source (Figure 5c), and by the orientation of lineated lavas,  
282 that clearly indicate lava transport direction (e.g., Chadwick et al., 1999). Both the  
283 bathymetry and the fault-parallel lineations demonstrate that they are topographically  
284 constrained and emplaced against fault scarps, typically <10 m in height (Figure 5).  
285 Based on the imagery throughout the study area (TowCam tracks and photomosaics,  
286 Figures 1, 2 and 4) sheet flows in general show orientation centered at ~5-15° NE (Figure  
287 6b), consistent with that of fault traces identified in high-resolution sonar data (Escartín  
288 et al., 2014) and with the overall orientation of the Lucky Strike ridge segment (~18° and  
289 ~19° NE respectively). This agreement suggests widespread lava steering by faults at the  
290 center of this segment over at least the last few tens of thousands of years, corresponding  
291 to the expected time span required to construct the seafloor in the study area. On Figure  
292 6b, the sheet flow lineation orientations along TowCam tracks display more variation  
293 than those from lava flows imaged by the photomosaics. This can be the result of local  
294 variations in the flow direction within lava flows, which typically flow subparallel to the  
295 ridge axis and faults, but instead flow off-axis, in directions oblique to sub-perpendicular  
296 to faults, such as those breaching faults and that are visible in the bathymetry (Fig. 3a).

297 While it is not possible to know pre-lava topography in this area, the high-resolution  
298 bathymetry constrains a range of plausible thickness along the axial lava flow. Based on  
299 the across-axis profiles, we estimate that the thickness of the youngest on-axis flow may  
300 vary between a minimum of ~2 m, and a maximum of ~10 m (profiles *p3* and *p5* in Figure

301 5b). With an average width of 50-75 m and a total length of ~2500 m (Figure 2a), we  
302 estimate minimum and maximum lava flow volumes of ~0.25 and  $1.9 \times 10^6$  m<sup>3</sup>. For  
303 comparison, these volumes are 1 to 2 orders of magnitude lower than the 2005-2006 axial  
304 eruption at 9°N along the EPR (Soule et al., 2007), or than other documented eruptions  
305 along the EPR, Juan de Fuca, and Gorda Ridges (Clague et al., 2017; see also compilation  
306 by Gregg and Fornari, 1998).

## 307 **6. Along-axis variations in mode of lava emplacement**

308 Seafloor imagery acquired on- and across-axis documents both the relative abundance of  
309 different lava morphologies, and their variation along-axis (Figures 1 and 6a). Sheet flows  
310 are the dominant mode of lava emplacement at the center of the study area, accounting  
311 for ~35% of characterized seafloor, locally exceeding >40% (Figure 6a). At the northern  
312 and southern ends of the segment, in contrast, sheet flows account for only ~10-20% of  
313 identified seafloor textures, while pillow lavas are most abundant (>40%; Figure 6a).  
314 Lobate flows, representing effusion rates intermediate between those of sheet flows and  
315 pillows, are present throughout, but are less abundant (~20% or less), and show no  
316 systematic along-axis variation (Figure 6a).

317 The towed camera photographed sedimented seafloor off-axis (Figure 6a), where the  
318 morphology of the underlying seafloor cannot be determined unequivocally. Fissures in  
319 these sedimented areas may reveal the underlying volcanic seafloor, under a thin  
320 sediment veneer (see supplementary material Figure S1b). In most cases the sediment

321 cover is thin, and efficiently covers flat sheet flows, while it cannot fully cover pillows  
322 and lobate lavas. This suggests that completely sedimented areas are likely sheet flows  
323 with a thin sedimented veneer, and therefore the relative abundance of sheet flows may  
324 be somewhat higher than indicated by the positively identified lava textures, particularly  
325 at the center of the segment (Figure 6a, S1b).

326 While the overall abundance of sheet flows increases towards the segment center, tracks  
327 CT09 and CT05 in Figure 6a, across the summit of the central volcano, show a local  
328 decrease in the abundance of sheet flows instead. The summit of the central volcano  
329 shows a complex recent history of volcanic emplacement that includes two volcanic cones  
330 (V1 and V2 in Figure 2) at two different stages of rifting (e.g., Escartín et al., 2015), leading  
331 to the formation of a depression hosting a fossil lava lake (Ondréas et al., 2009). These  
332 volcanic cones are built up by local lava emplacement dominated by pillows, but also  
333 sourcing and feeding the sheet flows which emanated from their base (Figure 2 and 3).

## 334 **7. Discussion**

### 335 *7.1 Sheet flows and along-axis fault steering of lava flows at slow-spreading ridges*

336 The eruption of pillow lavas which build both hummocks and axial volcanic ridges, is  
337 considered to be the main mechanism of upper volcanic crust construction at slow-  
338 spreading mid-ocean ridges. Our results suggest that along segments that are both  
339 magmatically robust and with associated along-axis variations in melt supply to the  
340 seafloor, this upper volcanic crust construction may be locally controlled by the

341 interaction of faults that steer lava flows along the ridge axis. This is also consistent with  
342 geological observations at the several magmatic ridge segments, particularly along the  
343 MAR (e.g., Ballard et al., 1979; Atwater 1979; Crane and Ballard, 1981; Gracia et al., 1998;  
344 Stakes et al., 1984), that report sheet flows at their segment centers reflecting focusing of  
345 melt, and enhanced delivery of lava to the seafloor, at these locations (e.g., Atwater, 1979;  
346 Gracia et al., 1998; Bideau et al., 1998).

347 The sheet flow abundance that we determine optically (~30-40% at the segment center,  
348 Figure 6) is much higher than that reported for some slow-spreading sites (e.g., 10-15%  
349 at the AMAR segment, Atwater, 1979; or ~10% at the Marianas 17°S segment, Asada et  
350 al., 2015) or fast ones (20% at EPR at 9°50'N, Kurras et al., 2000) and commensurable to  
351 the abundances reported along other areas of the EPR (~30-50%, White et al., 2002) or at  
352 Axial Caldera along the Juan de Fuca Ridge (~40%, Embley et al., 1990), sites that are  
353 extremely active magmatically. While there is no information on the orientation of  
354 lineated flows at other slow-spreading ridges, these sheet flows are commonly reported  
355 in low-lying areas at the feet of axial volcanic ridges and fault scarps (e.g., Stakes et al.,  
356 1984), as it is the case for the Lucky Strike flows (Figure 2).

357 Along-axis fault-control on the mode of lava emplacement at Lucky Strike is also  
358 consistent with a recent lava eruption identified along the Reykjanes Ridge (Crane et al.,  
359 1997), that is emplaced along a system of faults defining a graben, and that extends ~3  
360 km along-axis, a similar length to that of the axial flow at Lucky Strike (Figure 3a). This  
361 type of fault-controlled lava flow is also observed in terrestrial rift systems, mainly in the

362 AFAR area and along the East African Rift (Figure 7). As in the case of Lucky Strike and  
363 other slow- and ultra-slow volcanic ridge segments, volcanoes often develop at the center  
364 of rift zones, and are densely dissected by parallel fissures, faults, and grabens (e.g.,  
365 Dumont et al., 2019). For example, the recent lava flow SE of Hayli Gub volcano, shown  
366 in Figure 7a, flowed >15 km along the center of the axial graben (Barberi and Varet, 1971),  
367 while the several flows along the Dabbahu-Manda Hararo rift extend >10 km, also along-  
368 graben (Figure 7b). The interaction of lava flows with fault scarps, that is also observed  
369 at the East Pacific Rise (e.g., Escartín et al., 2007), probably results in the partial or  
370 complete burial of some tectonic features, and results in a significant underestimate of  
371 tectonic strain based on fault distribution and scarp height (e.g., Escartín et al., 2007;  
372 Medynski et al., 2016; Dumont et al., 2019).

### 373 *7.2 Changing modes of lava emplacement and Layer 2A properties*

374 The bathymetry and seafloor images (Figures 2, 3, 4 and 6) clearly show an along-axis  
375 transition from sheet- to pillow-dominated lava emplacement between the segment  
376 center and areas off to the North and South. This transition coincides with a larger-scale  
377 morphological change from smooth and regularly faulted terrain, to a rougher one  
378 dominated by hummocks and volcanic ridges. This likely reflects a gradual decrease in  
379 eruption rates (e.g., Gregg and Fink, 1995) away from the segment center, where the crust  
380 is thicker and the overall melt supply is inferred to be higher than at the segment ends.  
381 Off-axis camera tow images also suggest that these along-axis variations are persistent  
382 over time (Figure 6).

383 Differences in lava morphology (sheet flows vs. pillow lavas) probably result in a volcanic  
384 upper crust that differs depending on the dominant lava type, that may impact the  
385 seismic properties of Layer 2A (Figure 8a). Sheet flows efficiently fill fissures,  
386 depressions, and other small-scale topographic features. Successive sheet flows will  
387 therefore show a two-dimensional structure, with sub-horizontal interfaces (cracks), and  
388 a smooth, planar seafloor (Figure 8c left) as observed at the Lucky Strike segment (Figure  
389 2 a and b). In contrast, an upper crust dominated by the emplacement of pillow lavas will  
390 be associated with a three-dimensional porosity structure (sub-spherical spaces between  
391 pillows) and significant topographic relief (no lateral lava transport, local emplacement;  
392 Figure 8c right). Global seismic studies do not reveal a significant difference in overall  
393 Layer 2A seismic velocity across spreading rates and sites, possibly due to numerous  
394 other local factors that also impact seismic velocity, such as alteration, faulting, fissuring,  
395 hydrothermal activity, etc. (see Christeson et al., 2019, and references therein).  
396 Furthermore, lava flows, in particular lobate ones, may show significant voids due to lava  
397 drain and collapse of the volcanic surface. Site-specific studies are thus required to  
398 correlate local variations of seismic properties with other observables.

399 Figure 8c presents a simplified sketch of two end-member models and a transitional one,  
400 depicting the internal structure and nature of the volcanic upper crust and of the possible  
401 impact on Layer 2A seismic properties. These models may apply to different positions  
402 along the Lucky Strike segment and may be valid for other slow- and ultra-slow  
403 spreading ridge segments with locally high melt supply. For example, crack shape and

404 orientation have a strong control on seismic velocity, as well-aligned, elongated planar  
405 cracks efficiently slow-down wave propagation in directions perpendicular to them  
406 relative to units with equant porosity. At the same time, seismic velocity is also controlled  
407 by overall porosity. Hence, while an upper crust formed by successive sheet flows may  
408 have lower porosity and hence higher seismic velocities than a 'regular' ridge section  
409 with pillow lavas, the anisotropy associated with the sub-horizontal sheet flows (which  
410 may be assimilated to elongated cracks) may instead lower these seismic velocities in the  
411 vertical direction, perpendicular to flows (cracks). The presence of abundant sub-  
412 horizontal lava flows may also increase the internal seismic reflectivity of these units. The  
413 competing effect of porosity and crack shape on upper crust seismic structure may thus  
414 depend on the detailed internal structure of the upper crust that is formed through  
415 complex interaction of different modes of lava emplacement with faulting (Figure 8c).

416 Figure 8a shows the two-way travel time (TTWT) difference between the seafloor and the  
417 Layer2A/2B boundary identified along the axis of the Lucky Strike central volcano (Seher  
418 et al., 2010c). While the data shows significant scatter, there is a significant increase of  
419  $\sim 0.1$  km/s of the TWTT  $\sim 15$  km from the segment center (Figure 8a and b), and both  
420 towards the North and South. This TWTT may be attributed to an increase in Layer 2A  
421 thickness away from the ridge, to a reduction of the overall seismic velocity of this layer,  
422 or to a combination of both. Seismic velocity studies indicate an anomalously thick layer  
423 2A associated with the central volcano ( $\sim 750$ -800 m), as well as anomalously low seismic  
424 velocities ( $\sim 2$  km/s) that are attributed to the intense faulting (Arnulf et al., 2014). While

425 this excess Layer 2A thickness reported by Arnulf et al. (2014) is consistent with the  
426 presence of the central volcano, the TWTT increase away from the axis seems inconsistent  
427 with the focusing of melt to the segment center, where enhanced volcanism is expected,  
428 and the reduced melt supply at the segment ends where a thinner Layer 2A may develop  
429 instead. Therefore, this TTWT difference variation may be related to the change in the  
430 volcanic style instead of the Layer 2A thickness. With the increasing abundance of pillow  
431 lavas away from the segment center, that are associated with hummocky terrain and  
432 volcanic ridges, Layer 2A along the Lucky Strike segment may show lower overall  
433 seismic velocities, consistent with this TWTT difference increase (blue dashed lines in  
434 Figure 8a).

435

436 ***Acknowledgements:** This paper benefitted from datasets acquired during numerous cruises*  
437 *(Lustre'96, Gravituck'06, Bathyluck'08 and Bathyluck'09) and we thank the work of crews,*

672 *(numbered red lines), Nautilie submersible tracks (black lines) and VICTOR remotely operated*  
673 *vehicle tracks (blue lines). Numbered black circles indicate the location of images in Figure 4. b)*  
674 *Near-bottom multibeam bathymetry surveys (~1 m resolution) underlain by ship multibeam*  
675 *bathymetry (with transparency). The blue line shows the extent of the Lustre'96 DSL120 deep-*  
676 *towed sonar survey (Humphris et al., 2002; Escartín et al., 2014). Black boxes represent the*  
677 *location of Figure 2. See text and Supplementary Materials for details on cruises and datasets.*

678 **Figure 2.** *Shaded bathymetry (left) and slope (right) maps of the central section of the Lucky Strike*  
679 *segment (a and b), and of the rift valley floor towards the end of the segment (c and d). See Figure*  
680 *1 for locations. At the segment center (a and b), faults dissect two volcanic cones (V1 and V2) and*  
681 *crosscut a flat seafloor that is formed primarily by the accumulation of sheet flows (sf and pink*  
682 *shade in panel b; see text). This flat seafloor transitions to hummocks (h in panel b) and axial*  
683 *volcanic ridges towards the south, which are also faulted and fissured. This transition is indicated*  
684 *by the arrow labelled t. At the segment end (c and d) the seafloor is fully covered by hummocks,*  
685 *variably fissured and faulted. Hydrothermal deposits (h, orange transparency) are present at the*  
686 *center of the volcanic cones, and vents are indicated by red dots. Collapse pits are indicated by c.*  
687 *White and red boxes show the locations of Figure 3a, b and c, and the blue outlines in a) indicate*  
688 *the extent of seafloor optical photomosaics (pm).*

689 **Figure 3.** *a) Shaded high-resolution bathymetry (~1m resolution) of the Lucky Strike axis along*  
690 *the southern flank of the central volcano (location of panels a, b and c is shown in Figure 2b)*

691 showing the most recent axial lava flow (a and b), and older (more sedimented) lava flows (c), and  
692 associated volcanic structures. b) Detail of the terminal portion of the axial lava flow. c) Lava  
693 flows, showing folded textures, emplaced at the base of hummock mounds. Labels correspond to  
694 location of images in Figure 4 and profiles (p) in Figure 5. Blue lines indicate location of  
695 topographic profiles in Figure 5.

696 **Figure 4.** Examples of lava textures, tectonic and volcanic structures from seafloor imagery along  
697 the Lucky Strike segment. a) Photomosaic (ROV imagery) of the axial lava flow head, showing the  
698 main channel with lineations (yellow lines) and whorls (yellow dots at their centers), the broken-  
699 up lavas (jumbled or hackly lavas) at the flow edge (dashed white line), and the bounding fault  
700 scarp. b) Oblique view of axial lava flow (Nautile video grab, dive#1624). c) Partially sedimented  
701 and faulted off-axis sheet flow with lava coils, adjacent to a fault scarp to the right (OTUS  
702 photomosaic). d) Lobate flows (CT#7). e) Pillow lavas on the flanks of a volcanic ridge, elongated  
703 in the downhill flow direction (CT#4). f) Collapse pit along a dike-related graben system (OTUS  
704 photomosaic, Bathyluck'09). Locations of images are shown in Figs. 1 (d, e) and 3 (a,-c, f).

705 **Figure 5.** a) Profile along the center of the youngest axial flow, showing the location of the across-  
706 flow profiles in b) and two of the detailed along-flow profiles in c). b) Across-flow profiles show the  
707 change in morphology, from a wide flow with a collapsed central channel (p1) to an inflated flow,  
708 bound by fault scarps (p5-p6). c) Detailed along-flow profiles showing the amplitude (1-2 m) and  
709 wavelength (~10-20 m) of the folds in the surface of the lava flow (see Figure 3). The location of  
710 profile pc is shown in Figure 3c.

711 **Figure 6.** a) Along-axis bathymetry profile (top) and relative abundance of lava flow types along  
712 camera tow tracks CT01 through CT10 (locations shown in Figure 1a). b) Orientation of lineations  
713 identified both at camera tow tracks (CT#) and the photomosaics (PM) at the center of the Lucky  
714 Strike segment, and fault orientations digitized from side-scan sonar data (Escartín et al., 2014).  
715 For reference, the plot also shows the mean orientations of sheet flow lineations, faults, and the  
716 Lucky Strike segment (LS), indicated by inverted triangles, and the standard deviation when  
717 available (horizontal lines).

718 **Figure 7.** Recent lava flows, shaded in red, steered by fault scarps from the Afar region, a) along  
719 the rift extending SE of Hayli Gub volcano, and terminating and spreading at the sedimented  
720 Afrera Lake plain and b) along the Northern Manda-Hararo Rift, SE of Dabahu volcano. Satellite  
721 imagery: ©CNES/Airbus provided by Google Maps (accessed March 2021).

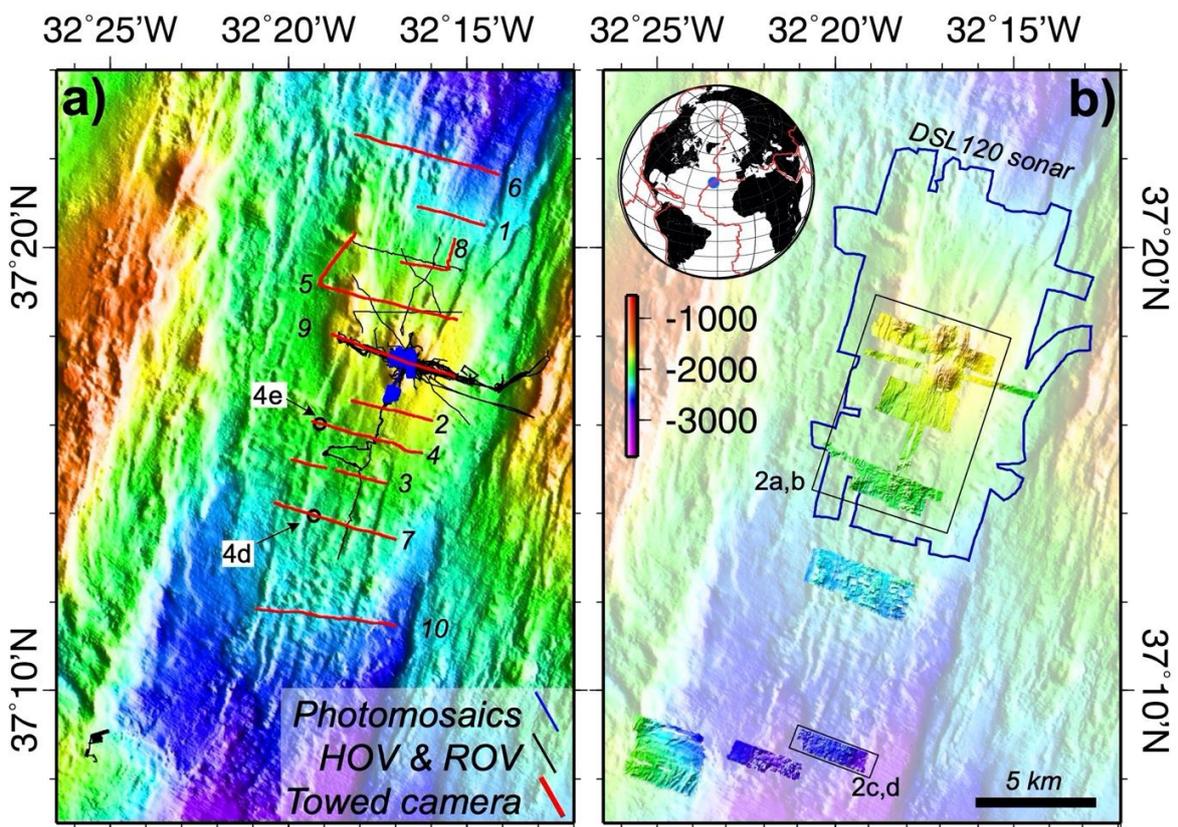

722 **Figure 8.** Geological interpretation of the upper oceanic crust, Layer 2A, at the Lucky Strike  
723 segment. a) Along-axis variations in Layer 2A two-way travel time (TWTT) difference between  
724 the seafloor and the Layer 2A/2B reflector (modified from Seher et al., 2010c). Towed camera  
725 transect numbers are indicated as TowCam track number). The red dashed line corresponds to the  
726 average TWTT difference for the segment center (sheet flow dominated), and the blue dashed lines  
727 highlight the gradients towards the N and S with increasing TWTT difference. b) Shaded  
728 bathymetric map from Seher et al. (2010c). c) Sketches showing the structure and construction of  
729 the upper oceanic crust at a slow-spreading ridge with high melt supply, from segment center to  
730 segment ends. Left: Sheet flow dominated seafloor, with interpreted high seismic velocity and low  
731 porosity. Middle: transitional crust between the end-members, characterized by a mix of sheet

732 flows deviated from the axis and ponding around axial volcanic ridges, and pillows accreting as  
733 axial volcanic ridges. Right: Axial volcanic ridge dominated seafloor, with feeding dikes. High  
734 porosity between pillows and may be associated lower seismic velocity. Colored arrows for each  
735 model are located along the axis (a and b).

## Supplementary information

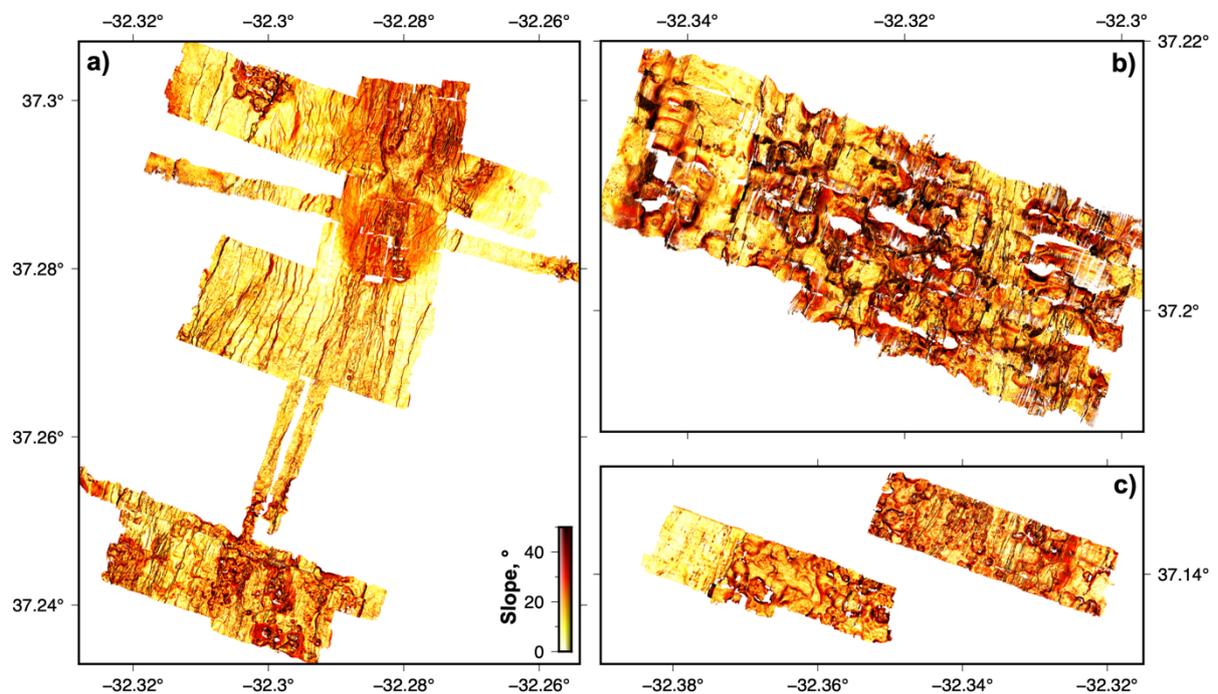

### 1. Supplementary figures

**Supplementary Figure S1.** A) Fissure cross-cutting sedimented pillows (CT07, N 37.22699°N 32.29971°W). B) Fissure on sedimented seafloor (no volcanic texture visible) but showing underlying sheeted flows (CT07, 37.23124°N 32.31598°W). C) Sheeted flow and hackly margin, found off-axis and partially sedimented (CT10, 37.19636°N 32.33184°W). D) Sedimented sheet flow with lava whorls (CT10, 37.19630°N 32.33115°W). White scale bar is ~10 m.

**Figure S2.** Bathymetry maps acquired during ROV Victor and AUV AsterX surveys along the Lucky Strike rift valley floor (see location in Figure 1).

**Figure S3.** Slope maps of the bathymetry shown in Figure S2, clearly revealing the differences in seafloor texture between zones dominated by lava sheet flows (north part of a) and areas dominated by hummocks and axial volcanic ridges (south of a and b, c).

## **2. Data used in this study**

Data were acquired over several cruises as follows:

1) During the **1996 KN145-19 "Lustre'96"** cruise (<http://www.marine-geo.org/tools/entry/KN145-19>) high-resolution side-scan sonar data were acquired with the DSL120 deep-towed sonar system. Black-and white vertical electronic still camera seafloor imagery was acquired with the deep-towed Argo-II camera system, in addition to observations during HOV Alvin dives.

2) During the **2006 Graviduck** cruise (doi:10.17600/6010110) vertical color seafloor digital imagery were acquired with the deep-towed TOWCAM system, while HOV Nautila acquired video imagery and recorded geological observations during dives.

Photomosaics for these camera tows were generated from vehicle navigation (layback and depth) and attitude (heading and altitude), and assuming a flat bottom. Images were not matched nor re-navigated owing to limited or no overlap along track.

Photomosaics have been tiled as geotiffs, and are publicly available: doi: 10.17882/80790

3) During the **MOMARETO, MOMAR'08-Leg1 and Bathyluck cruises** in 2006, 2008 and 2009 (dois 10.17600/6030130, 10.17600/8010110 and 10.17600/9030040, respectively), near-bottom, high-resolution bathymetry data were acquired with a multibeam system mounted on the ROV VICTOR 6000 and the AUV AsterX. ROV Victor also conducted geological surveys and observations, in addition to imagery surveys, using the OTUS black and white camera vertically mounted, to obtain photomosaics of the seafloor in 2008 and 2009. Open access links to bathymetry and photomosaics are indicated below.

Data publicly available and used in this paper include microbathymetry and seafloor photomosaics:

***High-resolution bathymetry.*** Near-bottom multibeam bathymetry data were processed post-cruise (cleaning, filtering, gridding), to obtain bathymetry grids at resolutions of either 1 m (surveys along the LS segment) or 0.50 m (survey at segment center acquired during photomosaic survey). The AUV or ROV was flown at ~70 m in average (varying between 50 to 100 m) for surveys with a resolution of 1 m per grid, and ~10 m for the surveys conducted in combination with optical imagery, and gridded at 0.5 m. Grids from different dives were manually shifted and adjusted to combine them into a single one in the central part of the segment (See Supplementary Figure S2a). Details of resulting grids and processing are partially published elsewhere (Escartín et al., 2015). Here we release the full set of near-bottom, AUV and ROV bathymetry grids: doi: 10.17882/80574

***Seafloor imagery and photomosaics.*** Vertically acquired imagery during ROV VICTOR6000 surveys and TOWCAM tracks were processed by the Girona University for illumination corrections, renavigation, and mosaicing. VICTOR survey processing included blending of imagery to obtain seamless photomosaics that facilitate their interpretation (e.g., Barreyre et al., 2012), while imagery from tracks were photomosaiced solely on navigation and altitude information (e.g., Escartín et al., 2008), with no blending; these mosaics provide information on scale and orientation of structures, even if images are not matched and blended locally. Details on mosaicing procedures are described elsewhere (e.g., Escartín et al., 2008; Prados et al., 2012; Barreyre et al., 2012).

The 2008 photomosaic is publicly available as a series of GEOTIF tiles at doi: 10.17882/77449

The 2009 photomosaic is publicly available as a series of GEOTIF tiles at doi: 10.17882/80447

The photomosaic from the Lustre'1996 cruise (Escartín et al., 2008) is publicly available at: [http://www.marine-geo.org/tools/search/Files.php?data\\_set\\_uid=6138](http://www.marine-geo.org/tools/search/Files.php?data_set_uid=6138)

**ROV and HOV observations.** ROV and HOV dives provided geological observations throughout the study area during different dives. All imagery available to us (still images and video) was examined to extract relevant geological observations (types of lava flows, orientation of structures, sedimentation, etc.). The observations of this study complemented those reported by the different science parties in each of the cruises listed above.

Video imagery along ROV Victor and HOV Nautille tracks from the 2006, 2008 and 2009 cruises can be made available upon request to J. Escartín.

**Acoustic backscatter:** Acoustic backscatter data acquired with the deep-towed DSL120 sonar was used to provide a broader context to the near-bottom bathymetry data, and to extrapolate observations among survey areas, as it has a more continuous coverage. Details on sonar data acquisition and processing are given elsewhere (Scheirer et al., 2000; Humphris et al., 2002; Escartín et al., 2014), and the gridded sonar data with a resolution of 10 m are publicly available at: [http://www.marine-geo.org/tools/search/DataSets.php?data\\_set\\_uids=7527,21460](http://www.marine-geo.org/tools/search/DataSets.php?data_set_uids=7527,21460)

Here we used this processed dataset, as well as its published tectonic interpretation (Escartín et al., 2014) for fault orientations.

**Identification and quantification of seafloor textures and flow lineations.** TowCam photomosaics were used for identification and classification of lava flow morphologies and sediment presence or absence, and for quantification of the resulting abundance of classes. For camera tows, the dominant seafloor texture was visually defined every 50 m along-track, identifying at the same the transitions, to define along-track segments. Each segment was attributed then a seafloor texture. Calculation of proportions along each TowCam track (Figure 6a) is then derived from the cumulative length of segments for each seafloor texture, normalized by the total length of each camera transect. No quantification of lava textures was done on the ROV OTUS photomosaics.

Where sheet flows with lineations were identified along the TowCam tracks, the most prominent structures were digitized to calculate their orientations. Due to the narrow across-track coverage of the seafloor, of approximately ~10 m, we were not able to map the full extent and limits of each flow. Hence lineations provide a flow direction locally, that we assume to be representative of the overall lava flow direction, that is dominantly along-axis (Figure 6b).
