Abstract

We report a detailed experimental investigation of the influence of the formation of nano-crystallites on the vibrational, electronic and optical properties of CrSi_2 thin films. Both amorphous and nanostructured thin films were investigated by means of electrical resistivity, Hall effect measurements as well as Raman and infrared spectroscopies. We show that both types of films exhibit a semiconducting-like behavior, with the notable difference that the high defect concentrations in amorphous films act as hole donors, modifying the electronic band structure and optical constants. The effect of the film thickness on electrical properties is well captured by the Fuchs-Sondheimer model indicating a decrease in the charge carrier mean free path, likely due to the formation of amorphous/nano-crystallite interfaces that contribute to strongly scatter the charge carriers. Raman spectroscopy performed on nano-crystallized thin films evidences the presence of a Raman-active mode at 229 cm^{-1} and confirms DFT calculations predicting a mode at 248 cm^{-1} , the observation of which had remained elusive so far in polycrystalline CrSi_2 . Measurements of the refractive index and dielectric constants of amorphous thin films show a very high refractive index in the mid-IR range. Our results illustrate how the controlled growth of nano-crystallites can be used to tailor the electronic, vibrational and optical properties of amorphous thin films.

1. Introduction

Transition metal silicides have been considered over the last decades as important technological materials, particularly in microelectronics¹⁻³. Among their numerous advantages, their high melting point, high thermal stability, and compatibility with silicon-based microelectronic devices explain the strong interest for these compounds. Moreover, the low cost and large abundance of silicon enables to consider large-scale development using its well-mastered processing technologies. While most of these compounds are metallic, some of them contain transition metals from group VI to VIII elements and exhibit a semiconducting or semimetallic behavior possibly accompanied by exotic magnetic or topological properties such as FeSi₂, MnSi_{1.7}, Ru₂Si₃ and CoSi^{4,5-7}.

Among these semiconducting silicides, chromium disilicide, CrSi₂, is a *p*-type narrow-band-gap material that remains chemically and thermally stable up to at least 1000 K under air^{8,9}. Due to its indirect bandgap measured to be about 0.35 eV^{10, 11}, low temperature coefficient of resistance¹²⁻¹⁴ and promising thermoelectric power factor ($PF = \alpha^2/\rho$) resulting from low electrical resistivity, ρ , and high Seebeck coefficient, α ,^{15, 16}, this compound has been considered for various applications ranging from IR detection^{10, 17, 18}, thin-film resistor in integrated circuits¹²⁻¹⁴, contact material in nanosystems¹⁹, Schottky junctions^{20, 21} or for thermoelectric power generation at high temperatures^{15, 16}.

Due to the high number of potential applications, a wealth of studies of the electrical properties of CrSi₂ in bulk polycrystalline and single-crystalline forms and in thin films have been reported. However, widely differing results were obtained, with ρ values ranging from 0.21 m Ω .cm²² to 18.5 m Ω .cm²³ at room temperature. This wide range of values can be explained by differences in deposition methods, heat treatments, film thickness and Cr:Si stoichiometry. Studies of thin films obtained by co-sputtering of Cr and Si²⁴⁻²⁷, evaporation^{13, 28, 29} or pulsed laser deposition

^{22, 30} at room temperature, have all reported the formation of an amorphous material. Partial or full crystallization of thin films were observed by annealing between 420 and 870 K, resulting in an increase in the ρ values ^{24-26, 28, 29, 31-33}. One possibility would be that high annealing temperature and duration may induce the formation of cracks due to thermal expansion and crystallographic orientation mismatches between the thin film and the substrate^{25, 26}. Nevertheless, the increase in the electrical resistivity with crystallization is mostly explained by charge carrier scattering at the amorphous phase – nanocrystallites interfaces^{24, 28, 29} and by the presence of acceptor-like extended or localized states near the valence band in the amorphous material disappearing by crystallization ^{32, 33}. Thus, the electrical properties of thin films are highly sensitive to the process route, heat treatments applied and to the nature of the substrate. Gong *et al* ²⁶ studied the influence of annealing on the electrical properties of sputtered CrSi₂ thin films deposited on Si(100) wafer with SiO₂ sublayer with thicknesses spanning the 40 – 90 nm range. An increase in ρ was observed after annealing 1 h at 573 K under nitrogen atmosphere, a behavior attributed to the full crystallization of the thin film with the formation of wide boundaries surrounding columnar grains. Recently, Burkov *et al* ²⁴ reported the study of CrSi₂ thin films with a thickness of 100 nm deposited by sputtering on oxidized Si wafer. Partial crystallization from 500 to about 900 K was shown to lead to the formation of non-percolating nano-crystallites within the amorphous matrix that behave as scattering centers. Concomitantly, enhanced α values were observed in this heterogeneous material, tentatively ascribed to an energy-filtering mechanism of holes.

Despite the abundant literature data available for CrSi₂, the physical properties of the amorphous phase have been only scarcely investigated ^{22, 25, 26, 29, 32, 34}. To the best of our knowledge, the vibrational properties were only measured by Koudelka *et al* ²⁷, while optical

properties have not been reported yet. Amorphous materials are characterized by the absence of long-range atomic order with a high number of dangling bonds acting as dopants. Moreover, disorder drastically alters the phonon properties, strongly scatters charge carriers, thereby reducing their mobility, and triggers the formation of long tails of localized states in the band gap of amorphous semiconductors. These effects can significantly impact the vibrational, optical and electrical properties of the materials. The control of interface charge carriers and phonons scattering mechanisms by structural defects or further nanostructuration is of great importance for some applications such as thermoelectricity^{35, 36}. It is therefore of prime interest to determine the influence of microstructure variations on the transport properties, a necessary step towards further development of nanostructured CrSi₂ for applications.

Here, we report a detailed experimental study of the influence of nano-crystallization on the vibrational, electronic and optical properties of CrSi₂ amorphous thin films elaborated by sputtering. Vibrational properties were studied by Raman scattering which evidenced, for the first time, the existence of a new vibrational mode of crystalline CrSi₂, which was previously predicted by DFT calculations³⁷. The electrical properties of both amorphous and nanostructured thin films were measured for film thicknesses ranging between 12 and 480 nm. We show that the effect of film thickness on the electrical properties is well captured by the Fuchs-Sondheimer model. The modification of the electronic structure and optical properties due to nanocrystallization are highlighted for the first time by IR reflectance and transmittance measurements.

2. Methods

2.1. Film elaboration. CrSi₂ thin films were deposited by sputtering with thickness ranging from 12 up to 480 nm on either glass substrates, CaF₂ substrates, or *p*-type Si(100) wafers (BT electronics, B doping), depending on the characterization technique used. Prior to deposition, the substrates were cleaned with acetone and ethanol in an ultrasonic bath during 1 min and dried under N₂. In the case of Si wafer, the native oxide layer was etched in a hydrofluoric acid solution (10 vol.%, 30 s) and a SiO₂ sublayer with a thickness of 30 nm was pre-deposited for electrical measurements. Scanning electron microscopy (SEM) observations evidenced a continuous SiO₂ sublayer, preventing a direct contact between the CrSi₂ deposited film with the Si wafer. A Plassys MP4505 RF magnetron sputtering (13.56 MHz) equipment was used for thin film deposition. The distance between the CrSi₂ target (Neyco 99.95 % purity, 3 in. diameter) and the substrate was about 5 cm. The base pressure in the chamber was 2×10^{-6} mbar before deposition. Argon gas (99.999 % purity) was used to create the plasma with a controlled pressure of 5.1 Pa. The sputtering power was set to 120 W. The target and the substrate were water cooled during sputtering. The film thickness was controlled by measuring the height of a step made by lift-off process using atomic force microscopy (AFM). Thermal treatments of thin films were performed during 1 h at 723 K in dynamic vacuum (10^{-4} mbar) with a heating rate of 100 K h⁻¹ and natural cooling. The temperature was controlled with a K-type thermocouple next to the sample.

2.2. Microstructural characterization. High Resolution Transmission Electron Microscopy (HRTEM) cross-section observations were performed using a JEOL 2200FS-200 kV equipment at the MEA platform, University of Montpellier. Prior to these observations, the CrSi₂ film deposited on a Si(100) substrate was prepared in cross-section by focused ion beam (FIB) on a FEI Strata DB 235 at IENM - Lille. Before etching the sample with the gallium ion beam, a

platinum layer, and a carbon layer were first deposited to protect sample surface. Atomic force microscopy (AFM) was performed in tapping mode with a Dimension 3100 AFM microscope from Brücker Instruments equipped with a nanoscope 3A quadrex. The tip used was a silicon pointprobe-plus from Nanosensors. Images of sizes $2 \times 2 \mu\text{m}^2$ and $5 \times 5 \mu\text{m}^2$ were recorded. Data were treated with the software Gwyddion³⁸ to determine the mean square roughness, R_{ms} .

2.3. Electrical measurements. Low-temperature in-plane electrical resistivity and Hall Effect measurements were performed from 80 up to 230 K for samples deposited on a Si/SiO₂ substrate in a Van der Pauw configuration with an Ecopia HMS 5000 equipment under air. Good electrical contacts were achieved using indium. A magnetic field of 0.5 T was used for Hall effect measurements. At high temperatures (300 – 700 K), in-plane electrical resistivity of thin films deposited on glass substrate was measured with a ZEM-3 (Ulvac-Riko) apparatus under a low helium pressure using a conventional four-probe method. Electrical contacts were ensured by deposited thin gold tracks on the thin films. The thin films were maintained in a vertical position using a dedicated sample holder (Ulvac-Riko).

2.4. IR and Raman measurements. Reflectance and transmittance infrared (IR) measurements were carried out with a 161 nm thick film deposited on a transparent CaF₂ substrate. The measurements were performed on the same film before and after annealing. IR spectra were recorded using a Bruker IFS 66 V Fourier transform spectrometer covering the 800–7500 cm⁻¹ spectral range. A black body source, a KBr beam splitter, and a Mercury-Cadmium-Telluride (MCT) detector were used. Room-temperature transmittance and reflectance measurements were performed using the reflection of a Transmittance Bruker accessory (A510 Q/T) with an angle of incidence (θ) of 11° placed in the sample compartment of the FTIR spectrometer. Micro-Raman spectroscopy experiments were conducted at room temperature on a 480 nm thick CrSi₂ film

grown on Si(100) substrate after annealing at 873 K for 20 min under Ar. A LabRam Aramis spectrometer from Horiba Jobin-Yvon was implemented using a He-Ne laser ($\lambda = 633$ nm). The beam power was set to 7.3 mW to avoid sample thermal heating.

3. Results and discussion

3.1. Thin film microstructure and effect of thermal treatment

The TEM cross-section images of a 45 nm thin film (deposited on Si(100) wafer) before and after annealing performed at 723 K for 1 h are shown in Figure 1. A typical columnar structure is observed for the as-deposited thin film with the presence of the native silicon oxide sublayer (~ 5 nm) at the substrate/film interface (Figure 1a). The electron diffraction pattern mainly consists in a large halo characteristic of the amorphous nature of the thin film (Figure 1b). The halo is located between inter-reticular distances of 1.80 and 2.37 Å. The intense and regular spots observed are characteristic of the single-crystalline Si(100) substrate.

The annealing step does not alter the columnar structure which is maintained (Figure 1c). A modification of the microstructure of Si is observed at the Si/CrSi₂ interface by TEM. This is due to Cr diffusion into the Si substrate up to about 10 nm as estimated by Electron Dispersive X-ray Spectroscopy (EDXS) analysis. Nevertheless, the diffraction pattern shows additional spots, evidencing the crystallization of the hexagonal CrSi₂ phase (Figure 1d). Their low intensity is attributed to the nanometer size of the crystallites, ranging from 3 to 10 nm. A weak diffuse halo is still observed. The annealed thin film is therefore made of CrSi₂ nano-crystallites embedded in an amorphous matrix.

Figure 1. TEM cross-sectional images of a 45 nm thin film deposited on a Si substrate: a) and b) as deposited, c) and d) after thermal treatment at 723 K for 1 h, and electronic diffraction patterns in the insets. The spots due to the Si(100) substrate are colored in red on the diffraction pattern of Figure d).

Because both the phonon and electron transport mechanisms can be modified by the surface roughness of the thin films, the root-mean-square roughness R_{ms} of the surface of the thin film was determined from the $2 \times 2 \mu\text{m}^2$ AFM images for the as-deposited and annealed films with thicknesses varying from 12 up to 164 nm (Figure S1 in Supporting Information). The evolution of R_{ms} as a function of the film thickness is reported in Figure 2. The R_{ms} values of the as-deposited amorphous thin films are low, varying from 0.5 up to 0.8 nm, and only weakly depend on the film thickness. After annealing, the R_{ms} values of the nanostructured thin films only slightly increase, with values ranging between 0.7 and 1.2 nm.

Figure 2. Roughness R_{ms} of amorphous (as-deposited) and nanostructured (annealed) CrSi_2 thin films. $\circ$ Amorphous films $\blacksquare$ Nanostructured films.

3.2. Vibrational properties of CrSi_2 thin films

At the Brillouin zone center, the optical phonon modes of crystalline CrSi_2 can be classified according to the irreducible representations of the D_6 point group $\Gamma = A_1 + 2A_2 + 4E_2 + 4E_1 + 3B_2 + 2B_1$. The E_1 representation is both infrared and Raman active. The A_1 and E_2 representations are Raman active while the A_2 representation is only infrared active. The B_1 and B_2 representations are silent. The frequencies of the silent modes have never been measured so far but they have been predicted by DFT calculations³⁷ at 204 and 300 cm^{-1} (B_1 modes), and at 238, 284 and 393 cm^{-1} (B_2 modes). The two infrared A_2 modes have been reported in the literature to be around 295 and 375 cm^{-1} , in agreement with calculations.

Raman spectra of as-deposited and annealed thin films of 480 nm thickness grown on Si(100) are shown in Figure 3 and are compared with that obtained for powders³⁷. For the as-deposited thin film, no lines are observed in agreement with its amorphous state, as previously reported by

Koudelka *et al* ²⁷. After annealing, the spectrum is composed of 6 Raman lines centered at 229, 300, 350, 394, 408 and 453 cm^{-1} . The contributions between 300 and 410 cm^{-1} have been reported in the literature on CrSi_2 thin films ^{11, 39}, powders ³⁷ and single crystal ⁴⁰ and their frequency positions are clearly identified (see Ref. ³⁷ for the assignment of these Raman lines). The Raman line at 229 cm^{-1} is unambiguously identified for the first time on a CrSi_2 film to be the E_1 mode predicted by DFT calculations ³⁷. Although this line has already been observed in single crystal ⁴⁰ and powders ³⁷, its significantly weaker intensity prevented any definitive conclusion to be drawn about its frequency position. Interestingly, an additional tiny Raman line can also be identified at 248 cm^{-1} in Fig. 3. This line had been previously observed only in powders ³⁷, but with a very low intensity. The fact that this line is experimentally observed on different samples and confirmed by first-principles calculations makes its assignment and position firmly established. The broad line observed at 453 cm^{-1} has never been reported in literature, should it be on thin films, powders or single-crystalline CrSi_2 . DFT calculations assign the 440 – 450 cm^{-1} range as either E_2 modes or longitudinal optical (LO) E_1 modes ³⁷. At this stage, these two possible modes cannot be distinguished, which will require additional polarization-like experiments.

Figure 3. Raman spectra of amorphous and nanostructured CrSi₂ thin films compared with that obtained on powders ³⁷.

3.3. Electronic properties of CrSi₂ thin films

3.3.1. Evolution of the electrical resistivity with temperature

The electrical resistivity, ρ , was measured from 300 to 685 K for a CrSi₂ thin film grown on glass substrate with a thickness of 480 nm. As shown in Figure 4, ρ does not significantly vary from room temperature up to 520 K, with a mean value of 0.46 m Ω .cm. This behavior, characterized by a low temperature coefficient of resistance ($TCR = 1/\rho \times \partial\rho/\partial T$), is consistent with an amorphous material ⁴¹. It should be noted that contrary to crystalline materials, a positive or negative TCR is not related to either a metallic or semiconducting state ⁴¹. Above 520 K, ρ significantly increases up to 0.94 m Ω .cm at 685 K. This behavior, similar to that reported previously for amorphous CrSi₂ thin films with a transition at temperatures ranging from 450 to

600 K^{24-26, 28, 29}, was attributed to the partial crystallization of the material. Upon cooling, ρ remains practically temperature-independent with a mean value of 0.94 m Ω .cm.

The electrical resistivity of bulk polycrystalline CrSi₂, reported by Dasgupta *et al.*⁴², increases from 0.9 m Ω .cm at 300 K to a maximum value of 1.8 m Ω .cm at 550 K, before decreasing at higher temperatures. These two distinct regimes correspond to the degenerate and intrinsic regime, respectively, of a semiconductor⁴³. Our results also show a positive TCR for CrSi₂ nanostructured films, about $5 \times 10^{-4} \text{ K}^{-1}$ around 300 K, in contrast to as-deposited amorphous films, but with values significantly lower than those reported in bulk CrSi₂ ($\sim 4 \times 10^{-3} \text{ K}^{-1}$ at 300 K)⁴². These results suggest that the nanostructured films are already above the percolation threshold after annealing at 700 K. This is in agreement with the work of Gladun *et al.*³¹, where a positive TCR for Cr_xSi_{1-x} films ($x = 0.115$ to 0.30) was measured after annealing at a temperature that was varying with x (at 573 K for $x = 0.3$ with $\text{TCR} \sim 3 \times 10^{-4} \text{ K}^{-1}$). They notably showed that this effect was related to the percolation of CrSi₂ crystallites formed within the amorphous matrix during annealing for $x > 0.11$.

Figure 4. Electrical resistivity ρ as a function of temperature for a CrSi₂ thin film with a thickness of 480 nm.

To better understand the origin of the increase in ρ after partial crystallization, the effective charge carrier density, p_H , and mobility, μ_H , were measured by Hall effect between 80 and 230 K. For the amorphous films, both $p_H = 1.0 \times 10^{23} \pm 0.5 \times 10^{23} \text{ cm}^{-3}$ and $\mu_H = 0.12 \pm 0.06 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ are thickness- and temperature-independent. This p_H value is in good agreement with that reported by Lenzlinger *et al*³³ for sputtered amorphous films on oxidized silicon wafer and is significantly higher than the values reported for bulk CrSi₂ ($p_H = 4 \text{ to } 6 \times 10^{20} \text{ cm}^{-3}$ ^{16, 44, 45}). Meanwhile, μ_H decreases by two orders of magnitude compared to bulk CrSi₂ for which $\mu_H = 12 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ⁴⁴. This low mobility can be attributed to the structural disorder inherent to amorphous compounds that strongly scatters the charge carriers. After partial crystallization, p_H decreases to $6 \times 10^{21} \pm 3 \times 10^{21} \text{ cm}^{-3}$, regardless of the thickness, and remains constant in the temperature range covered. This effect originates from the decrease in the defect concentration induced by crystallization and atomic rearrangement. In contrast, the observed increase in μ_H is no longer thickness-independent. The mobility values increase from

$\mu_H = 0.90 \pm 0.09 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ to $\mu_H = 1.40 \pm 0.16 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for 12 and 164 nm thick films, respectively. These values remain substantially lower than those measured in the bulk counterpart. It should be noted that μ_H values in CrSi₂ are highly related to the defect concentration as shown by Zhu *et al* ⁴⁶ who obtained $\mu_H = 1085 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for epitaxial films due to a lower defect concentration compared to the present sputtered amorphous and nanostructured films.

3.3.2. Influence of film thickness on the electrical resistivity

Figure 5 shows the evolution of the electrical resistivity as a function of temperature for amorphous and nanostructured thin films deposited on Si(100) wafers with SiO₂ sublayer with a thickness varying from 12 to 164 nm. For amorphous films, ρ increases with decreasing the thickness over the entire temperature range. This behavior is characteristic of charge carrier scattering at the film surface, as previously observed for example for Cu ⁴⁷, W ⁴⁸, Mo ⁴⁹ or CrSi₂ amorphous thin films ¹². In contrast, the thickness effect is less significant for nanostructured thin films. This different behavior cannot be explained by the surface roughness as similar R_{ms} values were measured for both films (see Figure 2). For this reason, we believe that charge carrier scattering mechanisms at the film surface are equivalent in both films. Nevertheless, the formation of nano-crystallites in the annealed thin film likely leads to an additional scattering mechanism at the amorphous matrix / nano-crystallite interface.

Figure 5. Evolution of the electrical resistivity ρ with the thickness of the CrSi₂ film for a) amorphous and b) nanostructured thin films.

To explain this behavior, we considered the well-known Fuchs-Sondheimer (F-S) model, which is based on the Boltzmann transport equation⁵⁰. This model is generally used to describe surface scattering of electrons in metallic thin films, and can be extended to semiconducting thin films by neglecting surface states within the flat-band approximation⁵¹. The F-S model, which assumes a single parabolic conduction band, a thickness-independent structural disorder, plane parallel surfaces and isotropic scattering processes⁵², yields the following equation:

$$\frac{\rho_{\infty}}{\rho} = 1 - \frac{3(1-p)}{2K} \int_1^{\infty} \left(\frac{1}{t^3} - \frac{1}{t^5} \right) \frac{1 - e^{-Kt}}{1 - pe^{-Kt}} dt$$

where ρ_{∞} is the electrical resistivity of an infinitely thick film with the same microstructure (including contributions from phonons, grain boundaries, impurities or point-defect scattering mechanisms), $K = d/\lambda_e$ where d is the film thickness and λ_e is the charge carrier mean free path in a bulk material with the same defect and impurity concentrations, and p ($0 \leq p \leq 1$) is the specularity coefficient describing the fraction of electrons that are specularly scattered from the surface. These scattered electrons have a conserved momentum and hence, do not contribute

to the electrical resistivity. In contrast, in the case of totally diffused scattering ($p = 0$), all the electrons are scattered with a random direction resulting in increased electrical resistivity.

In the present study, we tried to apply this approach to model the low-temperature experimental data measured on amorphous and nanostructured thin films. These data were fitted by a least-squares method using the Gauss-Newton algorithm to evaluate the values of ρ_{∞} and λ_e . Within this model, however, the value of p is usually unknown and strongly depends on the deposition method and substrate⁵³. In the case of copper thin films, for instance, Marom *et al.*⁵⁴ have shown that the scattering of electrons on smooth surfaces (that is, below the de Broglie wavelength) is mostly specular, synonymous with p values close to 1. In the present case, the R_{ms} values of the CrSi₂ thin films are low, varying from 0.5 to 0.8 nm and from 0.7 to 1.2 nm for amorphous and nanostructured thin films, respectively, that is, below the de Broglie wavelength of CrSi₂ estimated to be 5 nm⁵⁵. Based on this empirical criterion, we may therefore expect a mostly specular diffusion scattering in both cases, giving rise to high p values. Both p , and λ_e parameters cannot be independently determined by the F-S model^{56, 57}. Due to the lack of direct experimental probes to easily determine p , a totally diffused scattering with $p = 0$ is usually assumed in the literature^{12, 57-59}. For these reasons, we have implemented this model with several values of p varying from 0 to 1. As illustrative examples of the quality of the fits obtained, similar across the entire temperature range and for each p value, Figures 6a and 6b show the results obtained at 80 and 205 K assuming $p = 0$.

In the case of amorphous thin films, surface scattering occurs for thicknesses below about 45 nm (Figure 6a and 6b), thereby increasing the electrical resistivity of thinner films. This value is in good agreement with the thickness limit of 40 nm reported by Novikov *et al.*³². The estimated values of ρ_{∞} at each temperature are reported in Figure 6c and are similar for p value ranging

from 0 to 1 (Figure S2). The value of $\rho_{\infty} = 0.56 \text{ m}\Omega\cdot\text{cm}$ does not depend on temperature, which is consistent with the amorphous nature of the film, as previously discussed. In contrast, λ_e strongly depends on p , as shown in Figure 6d, resulting in charge carrier mean free paths that increase with increasing p , from $\lambda_e \approx 15 \text{ nm}$ for $p = 0$ up to $\lambda_e \approx 40 \text{ nm}$ for $p = 0.5$. These values are similar across the entire temperature range covered. A wide range of electron mean free paths in amorphous metallic films were reported in literature, ranging from 3 nm in $\text{Co}_{94}\text{Zr}_6$ films⁵⁸ (at 300 K, with $p = 0$) to 18 – 30 nm⁶⁰ in Y films (at 4.2 K, determined using another model) through 10 – 13 nm⁶¹ in Pt films (at 300 K, with p varying from 0.13 to 0.15). Based on these reported values, the large mean free paths obtained herein for higher p values, up to $\lambda_e = 240 \text{ nm}$ for $p = 0.9$, are unrealistic. For this reason, we have restricted our analysis to values of p near 0. These considerations thus suggest that diffused scattering of charge carriers prevails in amorphous films despite their low roughness, with $\lambda_e \geq 15 \text{ nm}$.

For nanostructured thin films, the values of ρ_{∞} are higher compared to amorphous thin films and slightly increase with increasing temperature (Figure 6c) from 0.78 m $\Omega\cdot\text{cm}$ at 80 K to 0.89 m $\Omega\cdot\text{cm}$ at 255 K (without any dependence on p). Figure 6d shows that the charge carrier mean free path is reduced for each value of p , compared to the amorphous thin films, with, for instance, λ_e decreasing from 15 nm to 3 nm if $p = 0$. We note that these values are in good agreement with the value of $\lambda_e = 2 \text{ nm}$ inferred by Trofimov *et al.* assuming $p = 0$ ¹² for nano-crystallized CrSi_2 thin films with thicknesses of up to 20 nm and crystallite sizes varying from 25 to 100 nm. The reduction in the charge carrier mean free path can be explained by the formation of nano-crystallites with sizes comparable to λ_e that induce additional charge carrier scattering at the nano-crystallites / amorphous phase interfaces.

The fact that a decrease in the charge carrier density is partially responsible for the increase in ρ_{∞} , and that the charge carriers mean free path is significantly reduced by scattering at the nano-crystallites / amorphous phase interfaces, explains why ρ is less influenced by the film thickness.

Figure 6. Experimental data (points) and fitted model (lines) of the electrical resistivity ρ as a function of the film thickness for amorphous and nanostructured thin films for $p = 0$ at a) 80 K and b) 205 K. c) ρ_{∞} values and d) λ_e values as a function of temperature for amorphous and nanostructured thin films with $p = 0$, $p = 0.3$ and $p = 0.5$. In the case of ρ_{∞} the points are nearly identical for each p value and cannot be clearly distinguished. $\circ$ Amorphous films $\blacksquare$ Nanostructured films.

3.3.3. Electronic structure

The optical electronic bandgaps, E_g^{opt} , of the thin films have been determined by IR reflectance and transmittance measurements for thin film with a thickness of 161 nm deposited on a CaF_2 substrate. The direct and indirect optical bandgap values have been determined using Tauc plots, a representation particularly well adapted for amorphous and nano-crystalline materials ⁶² :

$$(\alpha h\nu)^n = \beta(h\nu - E_g^{opt})$$

where α is the absorption coefficient, β is the band tailing parameter, $h\nu$ is the incoming photon energy, and n is a constant related to the transition process ($n = 1/2$ and $n = 2$ for indirect and direct transitions, respectively). Numerous models are used for the determination of α from experimental reflectance and transmittance measurements depending on the experimental conditions. After comparison of some models, we used the method of Galkin *et al.* ⁶³, the details of which are given in the Supporting Information Part 3. This model is adapted in the case of an absorbing thin film and considering multiple reflections in the thickness of the film and the substrate. The inferred values of α with the corresponding Tauc plots are shown in Figures 7a and 7b. A steep increase in α can be observed for photon energies above 0.23 and 0.43 eV for amorphous and nanostructured CrSi_2 thin films, respectively (Figure 7a). It clearly indicates a semiconducting nature of both materials, while a metallic behavior of amorphous CrSi_2 films was suggested based solely on electrical resistivity measurements ^{22, 29, 34, 64}. The non-zero absorption at low energies can be attributed to extrinsic absorption from free carriers. Tauc plots (Figure 7b) show that amorphous and nanostructured CrSi_2 thin films have indirect band gaps of $E_{g,ind}^{opt} = 0.15 \pm 0.01$ eV and $E_{g,ind}^{opt} = 0.20 \pm 0.01$ eV, respectively, and direct band gaps of $E_{g,dir}^{opt} = 0.59 \pm 0.01$ eV and $E_{g,dir}^{opt} = 0.63 \pm 0.01$ eV. The errors have been estimated from the

linear regression dependence on the selected data range. Thus, amorphous CrSi₂ thin films show a very low band gap value explaining the low electrical resistivity and nearly-metallic behavior. An increase in the band gap can be observed upon partial crystallization, although the value is not equivalent to that of crystallized CrSi₂ ($\sim 0.35 \text{ eV}^{10}$). This modified electronic structure is in agreement with the increase in the electrical resistivity and decrease in the charge carrier concentration measured experimentally, which can be attributed to the reduction of defect level and nano-crystallization during the annealing process. Such changes of the electronic structure of CrSi₂ thin films due to nano-crystallization are consistent with previous optical conductivity measurements²².

In contrast to crystalline materials that exhibit well-defined band gap edges, amorphous materials can be characterized by band tails due to structural defects⁶⁵. They are quantified by the Urbach energy, E_u , inferred from the exponential part of the absorption coefficient near the gap using the relation $\alpha = \alpha_0 \exp\left(\frac{h\nu}{E_u}\right)$. The value of E_u corresponds to the width of the tails of localized states near the band edge and are obtained from the plot of the variations in $\ln(\alpha)$ with $h\nu$ near the bandgap (see Supporting Information Part 4). Herein, a dramatic decrease of E_u by nano-crystallization is observed with values of E_u of 0.13 eV and 0.06 eV for as-deposited and annealed films, respectively, due to a decrease in the defect level. Thus, these band tails, nearly identical to the band gap values, can explain the quasi-metallic behavior of the amorphous thin films.

Figure 7. Optical properties of amorphous (as-deposited) and nanostructured (annealed) CrSi₂ thin films. a) Absorption coefficient and b) corresponding Tauc plot for both indirect and direct band gaps. □ Amorphous film, □ Nanostructured film. The black dashed lines show the linear fit of the Tauc plot.

3.4. Optical properties of amorphous and nanostructured CrSi₂ thin films

The refractive index, n , and extinction coefficient, k , shown in Figure 8a, were determined from the IR absorbance coefficients (see Figure 7a). The observed variations are in line with the electronic structure modifications induced by the nano-crystallization.

The behavior of n agrees with those reported for well-crystallized or epitaxial films and single crystals^{10, 63, 66}. A broad maximum is observed around 0.16 – 0.25 eV and 0.43 – 0.53 eV for as-deposited and annealed films, respectively. These energy windows are consistent with those reported in the literature for well-crystallized CrSi₂ thin films, extending from 0.3 – 0.55 eV¹⁰ to 0.47 – 0.56 eV⁶³. The energy shift of the maximum in n upon annealing is directly related to electronic structure modifications due to the change of inter-band transition as the band gap increases. Moreover, a large reduction of n values is observed after nano-crystallization, as expected from an increase in the band gap. Nevertheless, the n values of annealed CrSi₂ thin

films are still higher than those reported previously ^{10, 63, 66} because of the partial crystallization of the material after the thermal treatment. As for k , both amorphous and nanostructured samples show a similar behavior with a shift of about 0.25 eV. A large increase in k with decreasing the energy is observed, due to the absorption by free charge carriers ¹⁰. The slope of this part is higher for the amorphous thin film due to the high defect concentration. A minimum value of $k \approx 0.8$ is observed around 0.3 eV and 0.5 eV for amorphous and nanostructured thin films, respectively.

The real (ε_1) and imaginary (ε_2) parts of the dielectric function, were calculated from the n and k values using the following relations ⁶⁷:

$$\varepsilon_1 = n^2 - k^2$$

$$\varepsilon_2 = 2nk$$

The ε_1 and ε_2 values, reported in Figure 8b, are analogous with n and k . Broad maxima of ε_1 are observed at 0.16 – 0.25 eV and 0.43 – 0.53 eV for amorphous and nanostructured thin films, respectively, due to inter-band transitions. The ε_1 values are nevertheless larger in the case of the amorphous thin films. As for ε_2 , a large increase is observed at low energies, as previously described in the case of k .

Similarly to our results on nanostructured film, a maximum in ε_1 at about 0.5 eV is reported for epitaxial and polycrystalline CrSi₂ films ^{63, 66}, but with a smaller ε_1 value (near 50) due to the residual amorphous phase in our sample.

Figure 8. a) Refractive index n and extinction coefficient k as a function of the photon energy $h\nu$. b) Real and imaginary parts of the dielectric function ϵ_1 and ϵ_2 as a function of the photon energy. $\square$ Amorphous (as-deposited) and $\square$ Nanostructured (annealed) thin films.

4. Conclusion

Contrasting the electrical, vibrational and optical properties of as-deposited, amorphous and annealed, nanostructured CrSi_2 thin films have revealed interesting insights into the influence of nano-crystallites, successfully grown in the amorphous matrix through annealing for 1 h at 723 K under vacuum. Raman spectroscopy has evidenced a line at 229 cm^{-1} , predicted to be a E_1 mode by DFT calculations, that had remained elusive so far in experiments on thin films. In agreement with first-principles calculations, these measurements further enabled the identification of a weak Raman line at 248 cm^{-1} , which had been previously observed solely on polycrystalline CrSi_2 , but with a significantly lower intensity. The presence of high defect concentrations in amorphous films, acting as acceptor dopants, significantly increases the hole concentration to values usually encountered in metals. The amorphous nature of these films explains the strong lowering of the band gap width evidenced by optical spectra ($E_{g,ind}^{opt} = 0.15 \pm 0.01$) due to band tails that cover

nearly entirely the band gap ($E_u = 0.13$ eV). Upon annealing, the nano-crystallization induces a decrease in the defect concentration, leading to a concomitant increase in the band gap and reduction in the band tail width, in agreement with the measured lower carrier concentration. Thus, the increase in the electrical resistivity in partially-crystallized thin films can be explained by both the reduction of defect concentration by annealing, which modifies the electronic structure, and the formation of nano-crystallites that promotes an additional interface scattering mechanism reducing the charge carrier mean free path. Using the Fuchs-Sondheimer model, we showed that a charge carrier mean free path of $\lambda_e \geq 15$ nm in amorphous films is responsible for the variations in electrical properties as a function of the thickness by surface scattering that dominates for thicknesses below 45 nm. The variations in the electronic structure also manifest in the optical and dielectric constants. The decrease in the band gap in amorphous thin films produces a shift of the n, k, ϵ_1 and ϵ_2 constants towards low energy and a modification of their intensities. A large index of refraction n in the mid-IR range was obtained for amorphous CrSi_2 thin films, which can be of practical relevance to form waveguides for instance. Our study provides a robust basis to understand the vibrational, electronic and optical properties of both amorphous and nanostructured CrSi_2 thin films. In particular, our results demonstrate the possibility to tailor the electrical, optical and vibrational properties by controlling the crystallization rate during annealing and the thickness of the thin films for a given application.

Present Addresses

Adrien Moll – now at Univ. Paris Est Creteil, CNRS, ICMPE, UMR 7182, Thiais 94320, France

Author Contributions

The manuscript was written through contributions of all authors. All authors have given approval to the final version of the manuscript. The authors contributed equally.

ACKNOWLEDGMENT

The authors would like to greatly acknowledge Dr R. Viennois for fruitful discussions. Thin films were prepared at the Centrale de Technologie en Micro et nanoélectronique (CTM), Université de Montpellier, France. The authors would like to particularly thank F. Pichot for his precious help. They also thank D. Troadec (IENM, Lille, France) for the FIB sample preparation. This work was partly supported by the French RENATECH network. The authors also thank L. Daenes for Raman spectroscopy measurements performed at the Plateforme d'Analyse et de

Caractérisation Chimie Balard, Montpellier, France. Infrared Reflectance experiments were performed at the IR-Raman technological platform of the Université de Montpellier, France.
