Supporting Information

ABSTRACT: We show that reduced rhenium bipyridyl carbonyl complexes are stable and selective catalysts for deoxygenation of nitrous oxide (N₂O) in organic media in the presence of water. Mechanistic studies indicate that the Re complex is initially reduced to produce the activated species. Then N₂O binds to labile position at the reduced metal and the resulting adduct is further reduced to trigger N-O bond breaking and release of N₂. Proton donors are beneficial to enhance the catalytic rate and to reduce the energy required to generate potential limiting intermediate. These results open directions for N-O bond activation.

Keywords: N₂O, electrocatalysis, homogeneous catalysis, rhenium carbonyl, cyclic voltammetry, N-O bond activation.

Nitrous oxide (N₂O) is a gas being part of the biological denitrification process transforming nitrates into dinitrogen.¹ Its atmospheric concentration has increased in the last centuries due to extensive use of fertilizers and industrial processes.² It is an unhappy situation because N₂O is a greenhouse gas responsible for 4% of the additional greenhouse effect observed since the start of the industrial era.³ Moreover N₂O is transformed by photolysis in the stratosphere into nitrogen oxides involved in the catalytic cycles of ozone destruction making N₂O the main contributor to the destruction of the ozone layer of the 21st century.⁴ It is therefore of utmost importance to limit N₂O production and find efficient ways to reduce N₂O into N₂. N₂O is thermodynamically a good oxidant⁵ but a kinetically inert molecule. Its reduction resorts to small molecule activation via catalysis and can be viewed as a prototypical N-O bond activation process. Three enzymes have been reported to be able to reduce nitrous oxide, namely N₂O reductase enzymes.⁶ Catalysis of the reduction of N₂O can be performed using metal electrodes such as palladium, platinum, indium or iridium. However those metals are rare and expensive and the use of abundant metals suffers selectivity issues (competition with hydrogen evolution).^{7, 8} We thus turn to molecular catalysis where substrate, products, catalysts and intermediates belong to the molecular world. In that regards, numerous advances have been made in recent years in understanding the activation of C-O,⁹ O-O¹⁰ or P-O¹¹ bonds using molecular electrochemistry tools.^{12, 13} Much less is known regarding N-O bond. Although binding and activation of N₂O at transition metal centers has been studied and reviewed,^{14,15} there have been relatively few attempts to use, as molecular catalysts, low-valent transition metal complexes. Cofacial cobalt porphyrins have been shown to be active, albeit at moderate rates.¹⁶ Studies in aqueous medium have been carried out with nickel complexes on mercury electrode,¹⁷ but, as in the case of CO₂ reduction with nickel

cyclams,¹⁸ mercury seems to be playing a role in the process. When adsorbed on the surface of a graphite electrode, it has been shown that cobalt (II) tetraaminophthalocyanine behaves like a molecular catalyst reducing N₂O to N₂ in aqueous medium, but the proposed mechanistic analysis presents some inconsistencies and deserves to be deepened in order to better define the factors controlling the activation of the N-O bond.¹⁹

N₂O presents analogies to CO₂: the two molecules are isoelectronic, they have a central electrophilic atom and their reduction with two electrons leads to the rupture of an N-O or C-O bond and to the stabilization of the oxygen atom with two protons. Therefore, we reasoned that the principles at play for CO₂ to CO conversion with rhenium bipyridyl carbonyl complexes²⁰ could be a source of inspiration for N₂O to N₂ transformation.

Figure 1. CVs of (a) [Re(bpy)(CO)₃Cl] (1 mM) and (b) [Re(dmbpy)(CO)₃Cl] (1 mM), in acetonitrile with *n*-Bu₄NPF₆ (0.1 M) on a 3 mm diameter glassy carbon electrode. $\nu = 0.1$ V/s. Under argon (black). Under 1 atm N₂O (blue) and with increasing amount of water: 0.1 (red), 0.2 (green), 0.5 (magenta), 1 (dark yellow) M. $i_p^0 = 0.446 F S C_{\text{cat}}^0 \sqrt{D F \nu / R T}$. S is the electrode surface area, C_{cat}^0 is the catalyst concentration, D the catalyst diffusion coefficient, F the Faraday, R the gas constant, T the temperature.

We have found that $[\text{Re}(\text{L})(\text{CO})_3\text{Cl}]\text{metal}$ ($\text{L} = 2,2'$ -bipyridine (bpy) and 4,4'-dimethyl-2,2'-bipyridine (dmbpy)) exhibit efficient, selective and stable catalytic activity for reducing N_2O to N_2 in the presence of water. Figure 1 shows the catalytic currents observed in cyclic voltammetry (CV) with $[\text{Re}(\text{L})(\text{CO})_3\text{Cl}]$ in CH_3CN electrolyte in the presence of N_2O and increasing amount of water. In the absence of N_2O , the catalysts exhibit the classical behavior reported for such complexes (Figure S2).^{20, 21} A first one electron reversible reduction of the bipyridine ligand is observed. It is followed by a second reduction coupled to the chloride ligand decoordination. This second reduction is in competition with spontaneous dehalogenation of the bpy centered mono-reduced species which can dimerize to form a metal bonded Re-Re dimer.²¹ Therefore the stoichiometry of the second wave is less than one electron (see Supporting Information (SI) for simulations). Depending on the dryness of the solvent and supporting electrolyte, a third reduction wave corresponding to the dimer reduction can be observed at more negative potential (Figure S3). Upon saturation of the solution with N_2O , the first reduction wave remains unchanged but the second wave grows to reach a one electron stoichiometry (Figure S4). A new large wave appears at more negative potential (Figure 1). Control experiment shows that no such wave is observed in the absence of catalyst; the direct reduction of N_2O at the glassy carbon electrode occurs at more negative potential indicating that the overpotential has been reduced by ca. 500 mV (Figure S5). The catalytic wave exhibits the characteristic canonical S-shape of a fast catalytic process in the presence of excess of substrate. The steady-state nature of the catalytic current is confirmed by its invariance with scan rate (Figure S6). Interestingly we observed an increase of the catalytic current upon addition of water (Figure 1). As expected, $[\text{Re}(\text{dmbpy})(\text{CO})_3\text{Cl}]$ is reduced at more negative potential than $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ due to the electronic donating effect of the methyl substituent. We observed that the catalytic wave is at more negative potential with $[\text{Re}(\text{dmbpy})(\text{CO})_3\text{Cl}]$ than with $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ but more intense with the former compared to the latter (in similar conditions).

Figure 2. Controlled potential electrolysis at -1.72 V vs. SCE of a solution of $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ (90/10) + 0.1 M NBu_4PF_6 with $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ (0.5 mM) under 1 atm of N_2O on a 1 cm^2 glassy carbon electrode. Charge passed as function of time in the presence of catalyst (blue) and in the absence of catalyst (red).

Controlled potential electrolysis was performed at -1.72 V vs. SCE in a solution containing 1 mM of $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ in a $\text{CH}_3\text{CN}/\text{H}_2\text{O}$ (90/10) mixture under N_2O atmosphere. A stable current density of ca. $7.5 \text{ mA}/\text{cm}^2$ was measured for 90

min leading to a linear increase of the charge passed over time (Figure 2). Gas chromatography analysis of the gas headspace allows determination of the quantity of N_2 produced after passage of 20, 33.5 and 40 C (see SI for details of calculation) indicating a selective transformation of N_2O to N_2 according to:

No H_2 was detected. CVs run before electrolysis and passage of 40 C shows no significant degradation of the catalyst (see Figure S1). Control experiment at constant potential in the absence of catalyst confirm the absence of N_2O reduction at -1.72 V vs. SCE (Figure 2).

Figure 3. (a) CVs of $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ (1 mM) under argon (black) and under 1 atm N_2O at $v = 0.1$ (blue), 0.2 (red), 0.5 (green), 1 (magenta) V/s. (b) CVs of $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ (1 mM) under 1 atm N_2O (blue) and with increasing amount of water: 0.1 (red), 0.2 (green), 0.5 (magenta), 1 (dark yellow) M. $v = 0.1 \text{ V/s}$. Thick lines correspond to simulations according to equation (4). Solvent: acetonitrile with $n\text{-Bu}_4\text{NPF}_6$ (0.1 M). 3 mm diameter glassy carbon electrode.

Analysis of the CVs provides insights into the mechanism. We focus on $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ catalyst noting that the same features are observed with $[\text{Re}(\text{dmbpy})(\text{CO})_3\text{Cl}]$. As already mentioned, in the presence of N_2O the first reduction wave of the catalyst remains unchanged indicating the storage of an electron on the bipyridine ligand, i.e. formation of $[\text{Re}(\text{bpy}^{\bullet-})(\text{CO})_3\text{Cl}]^-$. The second wave, which stoichiometry is below one electron under argon due to partial formation of the dimer reaches a one electron stoichiometry under N_2O (Figure 3a). This suggests a fast addition of N_2O on the intermediate driving the reaction to the formation of $[\text{Re}^0(\text{bpy}^{\bullet-})(\text{CO})_3(\text{N}_2\text{O})]^-$ (Note that we do not speculate on the type of binding of N_2O on Re) and preventing formation of the dimer. However the wave does not shift significantly upon addition of N_2O indicating that N_2O binding occurs once $[\text{Re}(\text{bpy}^{\bullet-})(\text{CO})_3\text{Cl}]^-$ has been reductively dechlorinated thus creating a labile position on the reduced metal ready to binds N_2O . We also note that this second wave is not shifting significantly upon addition of water (Figure S7). Hence we propose that addition of water is not influencing the binding of N_2O on $[\text{Re}^0(\text{bpy}^{\bullet-})(\text{CO})_3]^-$. The catalytic process is triggered at more negative potential, suggesting that it is initiated by $[\text{Re}(\text{bpy}^{\bullet-})(\text{CO})_3(\text{N}_2\text{O})]^-$ reduction. This electrode electron transfer is slow and rate determining in the rising part of the catalytic wave as revealed by a sluggish rise of the current despite careful ohmic drop compensation. At large overpotential, a plateau current is reached indicating kinetic limitation by a chemical event. This chemical event involves water as co-substrate as the plateau current is increasing upon addition of water (Figure 1 and 3b). It can be proposed that the chemical event is a series of steps leading to (i) N-O bond

cleavage boosted by the presence of a proton donor (H_2O) and (ii) N_2 release. The resulting intermediate, $[\text{Re}^{\text{I}}(\text{bpy}^+)(\text{CO})_3]$, is likely reduced at the applied potential and then binds another N_2O molecule thus closing the catalytic loop. The proposed mechanism is summarized on Scheme 1.

Scheme 1. Proposed mechanism for N₂O reduction.

An apparent rate constant for the overall process, k_{ap} (s^{-1}), can be obtained from the plateau current assuming that the thermodynamically downhill electron transfer occurs homogeneously rather than at the electrode surface (see SI):

$$\frac{i_{pl}}{i_p} = 2.24 \sqrt{\frac{RT}{Fv}} \sqrt{2k_{ap}} \quad (2)$$

with

$$k_{ap} = \frac{k_1}{\left(1 + \frac{\sqrt{k_1/k_2}}{\sqrt{2} + \sqrt{k_2/k_1}}\right)^2} \quad (3)$$

where k_1 and k_2 are the apparent rate constant for the two chemical irreversible sequences of the catalytic loop shown on scheme 1.

The variation of k_{ap} with water concentration reported for both catalysts in Figure 4 shows a beneficial role of water on the chemical process characterized by k_1 . Fitting of k_{ap} vs. $[H_2O]$ using equation (3) and considering $k_1 = k_{1,0} + k_{1,1}[H_2O]$ and k_2 independent of $[H_2O]$ (vide supra) leads to the values gathered in Table 1. Note that this allows to estimate the maximal turnover frequency $TOF_{max} = k_1 k_2 / (k_1 + k_2)$ for any water content (for example, for $[Re(bpy)(CO)_3Cl]$, $TOF_{max} = 58.5 \text{ s}^{-1}$ in absence of water and $TOF_{max} = 1080 \text{ s}^{-1}$ with 1 M H_2O). The rate constant are larger with $[Re(dmbpy)(CO)_3Cl]$ than with $[Re(bpy)(CO)_3Cl]$, in line with the more donating electronic effect of dmbpy compared to bpy. Note also that the apparent rate constants for both $[Re(dmbpy)(CO)_3Cl]$ and $[Re(bpy)(CO)_3Cl]$ are much larger than the rate constants reported for cobalt porphyrins in benzonitrile with Bu_4NOH (of the order of 1 s^{-1})¹⁶

Table 1. Rate constants

catalyst	$k_{1,0}$ (s ⁻¹)	$k_{1,1}$ (M ⁻¹ s ⁻¹)	k_2 (s ⁻¹)
[Re(bpy)(CO) ₃ Cl]	60	1900	2400
[Re(dmbpy)(CO) ₃ Cl]	141	2600	8000

Figure 4. Apparent rate constant as function of added water obtained from equation (2) for the reduction of N_2O with $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ (blue) and $[\text{Re}(\text{dmbpy})(\text{CO})_3\text{Cl}]$ (red). The value in absence of water is arbitrarily plotted at $\log [\text{H}_2\text{O}] = -3$. Lines correspond to fitting with equation (3).

In the framework of the proposed reaction scheme, the catalytic wave in canonical conditions can be written as (see SI):

$$\frac{i}{i_p^0} \approx \frac{i_{pl}/i_p^0}{1 + \exp\left[\frac{\alpha F}{RT}(E - E_{ap})\right]} \quad (4)$$

with

$$E_{ap} + \frac{RT}{\alpha F} \ln \left(\frac{i_{pl}}{i_p^0} \right) = E_1^0 + \frac{RT}{\alpha F} \ln \left(\frac{k_S}{0.446 \sqrt{DFv / RT}} \right) \quad (5)$$

where E_1^0 , k_s and α are respectively the standard potential, the standard rate constant and the transfer coefficient for the reduction of $[\text{Re}^0(\text{bpy}^*)(\text{CO})_3(\text{N}_2\text{O})]^-$ identified as the potential limiting event. Fitting of the catalytic wave using equation (4) (Figure 3b and Figure S8)

leads to an evaluation of $E_1^0 + \frac{RT}{\alpha F} \ln \left(\frac{k_s}{0.446 \sqrt{DFv/RT}} \right)$ for

both catalysts as function of water concentration. It is remarkable that this quantity shifts anodically by 120 mV per decade of $\log[\text{H}_2\text{O}]$ (Figure 5). Unfortunately it is not possible to separate the thermodynamic parameter (E_1^0) from the kinetic parameter (k_s) from our experiments. However, besides the increase of k_{ap} (and $\text{TOF}_{\max}$), we reveal here an additional beneficial effect of water for N_2O reduction, via stabilization of the reduced intermediate $[\text{Re}^{\text{I}}(\text{bpy}^{\bullet-})(\text{CO})_3(\text{N}_2\text{O})]^{2-}$ with two water molecules, leading to an anodic shift of E_1^0 by 120 mV per decade of H_2O concentration, or via an increase of the standard rate constant by one order of magnitude per decade of H_2O concentration. This additional effect allows to reduce the potential to be applied to get a substantial current. The consistency of the whole analysis is checked by comparison of experimental data with numerical simulation of the catalytic wave using the extracted information (Figure S10).

Figure 5. Plot of $E_1^0 + \frac{RT}{\alpha F} \ln \left(\frac{k_s}{0.446\sqrt{DFV/RT}} \right)$ as function of added water for $[\text{Re}(\text{bpy})(\text{CO})_3\text{Cl}]$ (blue) and $[\text{Re}(\text{dmbpy})(\text{CO})_3\text{Cl}]$ (red).

Finally, we would like to emphasize that development of non critical metal complexes as catalysts would be necessary. Preliminary results show that $[\text{Mn}(\text{bpy})(\text{CO})_3\text{Br}]$ and $[\text{Mn}(\text{dmbpy})(\text{CO})_3\text{Br}]$ ²² are also active catalysts for N_2O reduction (Figure S11) but less efficient in terms of $\text{TOF}_{\max}$ than the rhenium complexes reported here. We are currently developing new sustainable metallic complexes to go in such direction.

In conclusion, we have shown that rhenium bipyridyl carbonyl complexes are stable and selective catalysts for deoxygenation of N_2O in the presence of water to form N_2 inert gas. Proton donors such as water are clearly beneficial to enhance the catalytic chemical rate but also the electrochemical limiting event as revealed by analysis of CVs. Compared to the direct reduction of N_2O on glassy carbon the overpotential is remarkably reduced by ca. 500 mV. There is however still plenty of room for improvement. These results should trigger further studies on electrochemical N-O bond activation using molecular catalysts.
