A Lithosphere–Atmosphere–Ionosphere Coupling Phenomenon Observed Before M 7.7 Jamaica Earthquake

MUHAMMAD ARQIM ADIL,¹ ERMAN ŞENTÜRK,² SERGEY ALEXANDER PULINETS,³ and CHRISTINE AMORY-MAZAUDIER^{4,5}

Abstract—The satellite-based earth observations have become an appropriate instrumental approach in monitoring the natural hazards among modern-day researchers. This study presents a multi-parameter approach using precursors of different physical nature defining the states of atmosphere and the ionosphere in terms of temporal and spatial variations about 5 days before the impending M 7.7 Jamaican earthquake (EQ). We performed a comprehensive analysis from the surface to the ionosphere at different altitude levels by analyzing the different datasets comprising, surface air temperature, relative humidity, total column water vapor, air pressure, Outgoing Longwave Radiations (OLR), and the total electron content of the global ionosphere maps (GIM-TEC). We observed a sharp increment in the atmospheric chemical potential (ACP) due to the increased radon activity that led to an abrupt decrement in the atmospheric relative humidity and, consequently, increased OLR that provides strong evidence of the air ionization production around the epicenter of M 7.7 EQ. Moreover, to check the periodicity of these atmospheric parameters, we performed a conflation analysis by meticulously analyzing these parameters in the same month and region for the previous 5 years during the non-existence of any major seismicity. This technique confirmed that the simultaneous atmospheric variations observed before the Jamaica EQ are not cyclic in the absence of significant seismic activities. The ionospheric conditions have also shown consistency with atmospheric disturbances, as depletions in GIM-TECs, having an amplitude of 4 TECU, are observed over the epicenter for 6 h (LT = 13–19 (– UT)) on January 23, 2020. Additionally, the vertical ionospheric and atmospheric profiles from FORMOSAT-7/COSMIC-2 (F7/C2), at different altitudes (75–225 km) over the EQ epicenter, showed significant depletions on January 23, 2020. These TEC variations are observed to be an effect of the vertical seismogenic electric field due to the

production of the air ionization at the atmospheric boundary layer by increased radon activity around the seismic preparation zone. The existence of these co-located synchronized atmospheric and ionospheric anomalies is explicitly and persistently local over a small region of the epicenter of Jamaican EQ that could be considered as potential short-term precursors. Also, these multi-observed anomalies will contribute to the physical explanation of the Lithosphere–Atmosphere–Ionosphere Coupling (LAIC) model.

Keywords: LAIC model, earthquake precursors, atmospheric and ionospheric interaction, FORMOSAT-7/COSMIC-2, 2020 Jamaica EQ M 7.7.

1. Introduction

The earthquake (EQ) phenomenon has a great contribution to aggregation and sudden energy releases to the atmosphere and ionosphere. The scientists often suggested that the EQs are extremely difficult to predict or even cannot be predicted due to their complex nature (Toker, 2021). Geller (1997) draws a completely pessimistic picture describing the attempts of EQ prediction, however, Keilis-Borok (2003) sees the perspective of prediction technology improvements in the nearest future especially taking into account that “the prediction of complex systems requires a holistic approach “from the whole to details” in consecutive approximations starting with the most robust coarse-graining of the processes considered”. His prophecy is confirmed by the recent advances in satellite-based observations that have provided extensive evidence in momentary anomalies proceeding EQs (Adil et al., 2021a, 2021b; De Santis et al., 2019; Hsiao et al., 2009; Oyama et al., 2011; Pulinets & Ouzounov, 2018; Şentürk et al., 2019). The existence of pre-EQ seismically induced atmospheric precursors can be found in various studies

(Blackett et al., 2011; Cervone et al., 2006; Mansouri Daneshvar et al., 2014; Ouzounov et al., 2007; Xiong et al., 2010). Similarly, many studies have widely reported the seismo-ionosphere anomalies (SIAs) as potential precursors to the EQs (Kamogawa, 2006; Liu et al., 2010; Pulinets & Ouzounov, 2018; Su et al., 2013; Yan et al., 2018; Zhou et al., 2017). Furthermore, the SIAs have engaged great controversy over the years, as some scientists (Masci & Thomas, 2014; Thomas et al., 2012) claimed that the SIAs reported by Pulinets et al. (2007) and Su et al. (2013) were largely contributed by global geomagnetic activity and they have no relationship to the seismic event. They also suggested that the physical mechanism behind the generation of these anomalies should be explained properly, as many researchers have directly related the ionospheric variations to some seismic events that cause ambiguity.

Some studies have explained the physical mechanisms behind the generation of these ionospheric anomalies (De Santis et al., 2015; Freund et al., 2009; Kamogawa, 2006). Pulinets and Ouzounov (2018) suggested that substantial radon tends to be released during tectonic plate motion where various gases such as carbon dioxide, helium, methane, and hydrogen serve as carriers disclosing it to the atmosphere. These radon emanations lead to air ionization, and with the condensation of water vapor, latent heat of vaporization is produced, which is responsible for atmospheric disturbances. The SIAs are the results of variation in the atmospheric electric field caused by the formation of ion clusters at the atmospheric boundary layer producing the local modification of the Global Electric circuit, which are reflected in the ionosphere as the large-scale ionospheric irregularities (Pulinets & Davidenko, 2014). On the other hand, Kuo et al. (2014) proposed a LAIC model explaining the formation of the vertical electric field due to the production of positive charges over the Earth's surface. They suggested that this electric field elevates the vertical current flow to the upper atmosphere. The positive and negative ions present in the ionosphere are enforced to undergo upward-downward flows. This process initiates the movement of plasma bubbles which may be responsible for TEC variations. Here, one should keep in mind the limitations of the proposed mechanism of Kuo et al. (2014) because of

the following facts: (1) the “positive holes” effect is a substantially solid body phenomenon, which cannot be generated and observed over the ocean areas regardless many EQs have their epicenters in oceans and pre-EQ ionospheric anomalies are equally observed over ocean EQs as over the land; (2) plasma bubbles are essentially equatorial ionosphere phenomena that do not develop in the middle and high-latitude ionosphere, where pre-EQ anomalies are observed as well.

Many studies have presented different multi-instrumental approaches in pursuit of physical and chemical changes that may arise before an EQ activity. Ouzounov et al. (2011) reported some morphological features, like variations in ionospheric TEC and atmospheric parameters about 5 days prior to the 2011 M 9.1 Tohoku-Oki EQ. Similarly, some strong collocated perturbations in ionospheric TEC and different atmospheric observables were observed about 2–3 months before the impending M 7.5 Indonesia EQ, however, these anomalies were not obvious ones but possibly associated with this EQ (Marchetti et al., 2020). Also, some significant enhancements/depletions in multi-atmospheric parameters along with ionospheric variations were statistically detected as possible precursors about 25–30 days before 2010 Illapel EQ (Mansouri Daneshvar & Freund, 2017). Despite all of these studies, there is still a lack of conclusiveness. We believe that the only way to study the range and impact of the seismically induced perturbations is to start analyzing from ground level.

Our approach is based on the understanding that the seismic preparation area is the center stage for the interaction of the different geophysical shells. The system of geophysical shells (lithosphere, neutral atmosphere, and ionosphere) can be analyzed as an open nonlinear system. Internal dissipation within the system together with correlated interaction of its elements, a process of self-organization can occur due to intensive exchange of matter and energy with the environment in non-equilibrium conditions. These processes accompanied by the synchronization of the geosphere's characteristics could lead the system to a critical state. The synchronization of the geosphere's characteristics can be spatial, temporal, or spatio-temporal. The main purpose of this paper is

not only the demonstration of the multiparameter approach but to reveal the synchronization in time and space of different atmospheric and ionospheric parameters that testifies the approaching of the system to the critical point. As an example of our approach, we present the analysis of the seismically induced perturbations from ground level to the ionosphere as potential precursors to the recent 2020 M 7.7 Jamaica EQ. This EQ is reported as one of the largest ones occurring around the world in 2020 and the largest one in the Caribbean since 1946. The data and methodology adopted in this study are briefly described in Sect. 2. The results are given in Sect. 3 and discussed in Sect. 4. Finally, conclusions are provided in Sect. 5.

2. Data and Methods

2.1. Data Preparation

In this study, the spatial and temporal variations in the lower atmospheric and the ionospheric parameters are analyzed over the epicenter of M 7.7 Jamaican EQ. Figure 1 shows the epicenter of M 7.7 Jamaica EQ along with the tectonic settings of its surrounding areas. This EQ (19.419° N 78.756° W) was occurred on January 28, 2020, at 19:10 UT, having a depth shallower than 20 km in the northwest of the Lucea, Jamaica. The region of the EQ is controlled by the motion of the North America and Caribbean tectonic

plates, where the North America plate moves towards the west-southwest to the Caribbean plate at a rate of approximately 19 mm/year. The rupture was left-lateral towards the east-northeast indicating a strike-slip fault mechanism. The fault plane extending approximately in the east–west direction is in line with the orientation of the regional plate boundary (U.S. Geological Survey, 2020).

To analyze the atmospheric composition during the seismic activity period, we analyzed the temporal variations of atmospheric relative humidity, surface air temperature (SAT), and total column water vapor for January 2020 through NASA’s online database (<https://gmao.gsfc.nasa.gov/>). Furthermore, to check and validate the novelty of any variation in these datasets as a seismic influence, we constructed the confidence bounds based on the median (M) and interquartile range (IQR) for a period of 5 years in the same month January without any significant seismicity. For the construction of these bounds, the time series should be ordered in ascending ($x_1, x_2, x_3, \dots, x_{27}, x_{28}$), where x values correspond to the daily data for a fixed epoch within 28 days. The lower quartile Q_1 , middle quartile Q_2 , upper quartile Q_3 , and interquartile range (IQR) are calculated to determine upper and lower bounds using Eqs. 1–4.

$$Q_1 = \frac{x_7 + x_8}{2} \quad (1)$$

Figure 1

Spatial distribution of the strong ($M \geq 7$) earthquakes (from http://www.geologie.ens.fr/~ecalais/_Media/map_large.jpeg) that occurred in the Caribbean basin. The focal mechanisms of the earthquakes are marked by color (see legend inside the figure). Black lines indicate the faults (<http://www.geologie.ens.fr/~ecalais/research/the-january-28-mw78-cayman/>)

$$Q_2 = M = \frac{x_{14} + x_{15}}{2} \quad (2)$$

$$Q_3 = \frac{x_{21} + x_{22}}{2} \quad (3)$$

$$IQR = Q_3 - Q_1 \quad (4)$$

The lower (LB) and upper bounds (UB) for the outlier test are as follows (Varotsos et al., 2017):

$$UB = M + 2IQR \quad (5)$$

$$LB = M - 2IQR \quad (6)$$

Equations 5–6 declared that, with a 99.63% confidence level, either observed values falling over these bounds will be declared as an abnormal value.

The spatial anomaly datasets of several variables, including SAT, relative humidity, air pressure, and outgoing longwave radiations (OLR) at different analysis levels, like, at the surface (0 km from mean sea level), 7 km, 9 km, and 12 km above mean sea level respectively, were retrieved from National Oceanic and Atmospheric Administration-Physical Sciences Laboratory (NOAA-PSL) via <http://psl.noaa.gov/data/composites/day>. We performed a subtraction method to eliminate the seasonality of the datasets, where the anomaly map of each observed day, was subtracted with the mean of the previous 5 days (Freeshah et al., 2021), as represented by Eq. 7:

$$\mu_{res} = \mu_{obs} - \frac{\sum_{k=1}^n (\mu_k)}{n} \quad (7)$$

where μ_{obs} is mean anomaly map for the observed day and μ_{res} is the resultant mean anomaly map of the desired parameter. According to Dobrovolsky et al. (1979), the area of the EQ preparation zone is defined by the formula given as $r = 10^{0.43M}$, where M represents the magnitude of the EQ and r represents the radius of the preparation zone. According to this formula, the radius of the Jamaican EQ extends to ~ 2046 km, which covers an area of almost 0–36° N in latitude and 58–98° W in longitudes. All the spatial and temporal datasets were retrieved, specifically, in the region of $\pm 10^\circ$ around the epicenter that falls within the EQ preparation zone.

Now, to explore the ionosphere conditions, we considered GIM-TEC maps with a spatial resolution

of 2.5° and 5.0° (Latitude, Longitude) having a temporal resolution of 2 h from Jet Propulsion Laboratory (JPL) via <ftp://gssc.esa.int/gnss/products/ionex/>. JPL GIMs are known to have an accuracy of approximately 4–5 TECU globally (Hernández-Pajares et al., 2009), and 2–3 TECU in the low latitude region and under low solar activity (Wielgosz et al., 2021). One may also use two convenient methods named auto-covariance estimation of variable samples (ACEVS) and differential areas for differential stations (DADS) to reveal ionospheric anomalies under stationary conditions (Yuan & Ou, 2001, 2002). The TEC describes the total number of electrons in a cylinder with a one-meter square base area throughout the line of sight (LOS) connecting the satellite and the receiver. It is represented in TECU units, where one TECU is equal to 10^{16} electrons per meter square. Since the ionosphere is largely influenced by solar and geomagnetic activities (Afraimovich & Astafyeva, 2008), therefore, the solar index F10.7 and the geomagnetic Kp and Symmetric-H (SYM-H) indices are used to distinguish the global from the local effects.

2.2. Calculation of F7/C2 vertical TEC profiles

We utilized the atmospheric and ionospheric data of FORMOSAT-7/COSMIC-2 (F7/C2) to cross-check and reinforce our results. The COSMIC-2 mission was launched on June 25, 2019, and planned as a continuation of the COSMIC-1, consisting of six satellites into low-inclination orbits for observing and monitoring the global meteorology, climate, and the ionosphere. The six satellites collect weather data between $\pm 50^\circ$ of the N–S latitudes and provide more than 4000 atmospheric/ionospheric profiles each day (Schreiner et al., 2020). F7/C2 provides the ionospheric observations of radio occultation (RO) such as the electron density, relative TEC, and S4 index from ~ 70 km in altitude to LEO orbit. We used the TEC data of two GNSS ROs, G07 and G28, which are located near the epicenter. Also, the ionospheric TEC maps over the epicenter were analyzed from 75 to 225 km on January 23 (anomaly day). These maps were constructed from TEC profiles of GNSS ROs that were located in the EQ preparation zone. The ionospheric data was obtained

from the ionPrf files from <https://data.cosmic.ucar.edu/gnss-ro/cosmic2/nrt/>. The calibrated occultation TEC values in the GNSS RO technique are calculated from the calibrated phase (ΔL) using the following formula, where f_1 and f_2 are the carrier frequencies of L1 and L2 signals, respectively.

$$TEC_{calibrated} = \frac{\Delta L_{calibrated}}{40.3 \times 10^{16}} \times \frac{f_1^2 f_2^2}{f_1^2 - f_2^2} \quad (8)$$

We used the calibrated TEC for the reconstruction of the electron density profiles. Firstly, the electron density at the orbit altitude is determined by linear regression of the square of the calibrated TEC for the top few kilometers of the tangent point. TEC near orbital altitude is extracted by the following formula where p is the impact parameter, N_e is the electron density, and p_{max} is the maximum impact parameter which is approximately equal to the orbit radius.

$$TEC(p) \approx 2N_e(p_{max}) \sqrt{2p_{max}(p_{max} - p)} \quad (9)$$

The calibrated TEC is spline interpolated to the regular grid of impact parameters on the occultation side, and it is inverted to an electron density profile using Eq. 10 (so-called onion peeling method) where p_i is equal to p_{max} at the orbit altitude.

$$N_e(p_i) = \frac{3}{4} \frac{TEC(p_i)}{\sqrt{2p_i(p_{i+1} - p_i)}} - \sum_{k=1}^{n-i} c_{k,i} N_e(p_{i+k}) \quad (10)$$

The coefficients, $c_{k,i}$ are derived in Syndergaard et al. (2005). F7/C2 vertical TEC profiles are calculated using the integration of the electron density profiles from 80 km to orbit altitude where negative values of electron density are not included.

The atmospheric profiles such as temperature, pressure, water vapor pressure, and vertical refractivity index can be obtained from the surface up to 60 km with a vertical resolution of 0.05 km using wetPf2 files (Ho et al., 2020). We investigated the air temperature and pressure data of F7/C2 from January 20 to January 28 with analysis levels at the surface and 300mb (~ 9 km), respectively. The data covers 10–30°N latitudes and 70–90°W longitudes.

2.3. Exploration of LAI anomalies: approach

It is indispensable to comprehend the associated processes and the geology around the EQ preparation zones to attain sturdy insight into the induction of seismic anomalies that further interact with the atmosphere. Radon emanations from rocks due to stress effect along fault lineaments had widely reported as a potential seismically induced gas (Giuliani et al., 2009; Hauksson, 1981; King, 1981; Richon et al., 2003; Woith, 2015). Moreover, the increased radon discharges from macroscopic faults (such as an EQ activity) have been proved experimentally (Mollo et al., 2011; Tuccimei et al., 2010). Pulinets et al. (2015) proposed a mechanism describing that the radiation ionization associated with radon gas initiates several chemical and physical processes in the atmosphere. The condensation of water vapor takes place due to the formation of large clusters of ions as a result of the chemical reaction and ionization process. This water vapor condensation is further responsible for the release of latent heat of vaporization at a large scale. These plasma-chemical compositions produced by increased radon emanations are responsible for variations in air temperature and relative humidity over a seismically active region (Dunajacka & Pulinets, 2005; Ouzounov et al., 2018; Pulinets et al., 2015). Furthermore, Planinić et al. (2001) observed and reported an anticorrelation between radon and air pressure during the analysis of long-term data of 2 years between 1999 and 2000 before some EQs. They claimed that increasing radon was observed to cause significant depletion in air pressure before the analyzed EQs. Due to these atmospheric circulations, the latent heat releases that further generate some extra heat flux that could be enveloped in the form of OLR. OLR is the thermal radiation egress from the top of the atmosphere (10–12 km) that establishes a connection with the earth-atmosphere system and depends on the SAT (Ouzounov et al., 2007). Now further, the varying air humidity and the radioactive decay of radon releasing α -particles are the main source of air ionization which further contributes to the formation of the ions of aerosol-size particles. Boyarchuk et al. (1998) performed some numerical calculations that resulted in changing the atmospheric electric field in the

Figure 2

The solid blue line represents the SAT mean values for the 5-years between 2015 and 2019. Similarly, the pink solid line indicates the SAT time series for January 2019 as a conutation analysis. The solid and dashed-dotted black lines denote the corresponding UB and LB, respectively. **b** the temporal variations of the ACP datasets for the month of January 2020, where a solid black line represents the corresponding UB. The dashed red line represents EQ day. The yellow area represents anomalous activities well exceeding the corresponding UB and LB

presence of the aerosols flux. The varying atmospheric boundary layer conductivity having anomalous atmospheric electricity is mainly responsible for the ionospheric irregularities. The physical interpretation of this phenomenon was further carried out by Kuo et al. (2014) that explained the ionospheric perturbations influenced by this electric field.

Besides, previous studies were very limited to the investigation of a couple of parameters or sometimes to an individual parameter without using multi parameters to show any correlation within different layers of the geosphere. In this study, we will not only demonstrate the multiparameter investigation but also reveal the synchronization in time and space of different atmospheric and ionospheric parameters that testifies the approaching of the system to the critical point. In addition, we are undertaking long-term temporal datasets to investigate the novelty of the results by expanding the analysis to those without significant seismicity periods to confirm the non-existence of such anomalies. Due to the lack of data

availability, we were unable to accumulate the direct radon measurements around M 7.7 Jamaican EQ. However, as the increased radon flings along the macroscopic fault lineaments have proved experimentally by Mollo et al. (2011), we have considered all those parameters that are directly or indirectly related to increased radon emissivity and may play an important part in EQ forecasting. On the other hand, during the air ionization process produced from increased radon activity, the latent heat of vaporization is equal to its chemical potential at phase transition (Pulinets et al., 2015). According to Boyarchuk et al. (2006), for a given relative humidity (H) and SAT (T_g), the correction of the chemical potential of the atmosphere can be calculated as:

$$\Delta U = 5.8 \times 10^{-10} (20T_g + 5463)^2 \ln(100/H) \quad (11)$$

We estimated the atmosphere chemical potential (ACP) with temporal datasets of the atmospheric relative humidity and SAT for January 2020 using the

The solid and dashed-dotted black lines denote the corresponding UB and LB, respectively, in both panels. The dashed red line represents EQ day. The yellow area represents anomalous activities well exceeding the corresponding UB and LB

Eq. 11, which can be interpreted as the increased radon activity.

3. Results

Radon during its decay emits energetic α -particles with the energy $E_\alpha = 5.46$ MeV. Since the energy of atmospheric gas ionization lies within the range of 10–30 eV, each α -particle can produce on average $\sim 3 \times 10^5$ electron–ion pairs (Pulinets et al., 2015). After the series of plasma chemical reactions, the primary ions form the positive and negative terminals which start to be hydrated by the attachment to the water molecules present in the atmospheric air. During every act of water molecule attachment, it emits at least the thermal energy of 0.433 eV called the latent heat of condensation. By this process, the free water vapor is removed from the atmosphere

resulting in the humidity drop, and latent heat release leads to an increase in the air temperature. The latent heat of vaporization is equal to the ACP during its phase transition. In this sense, the ACP can be regarded as the increased radon activity. Figure 2 represents the temporal variations of the ACP data for the month of January 2020. One can observe that the ACP abruptly increase to attain a value of 0.014 eV on January 23, 2020 (Fig. 2b), which suggests an increased radon activity around the epicenter of the M 7.7 EQ.

In comparison to normal circumstances, the increased radon coalescence yields a drop in relative humidity and consequently alters air temperature (Pulinets et al., 2015). From Fig. 3, one can see the temporal dynamics of the relative humidity on the epicenter of the Jamaica earthquake where during one and half days, from 21:00 UT on 21 January to 09:00 UT of 23 January, the relative humidity dropped

Figure 4

Short-term Spatio-temporal anomaly maps of mid-tropospheric relative humidity from NOAA, at an altitude of 7 km above mean sea level, between January 19 and 30, 2020. The epicenter of M 7.7 EQ is represented by a white star. The dashed-red square exhibits the anomalous day

to $\sim 50\%$ from $\sim 85\%$. Similarly, Fig. 4 describes the spatial distribution of the mid-tropospheric relative humidity where it significantly dropped to $\sim 25\%$ on January 23, compared to the other days (5 days before the EQ), over and around the epicenter of M 7.7 Jamaica EQ. On the other hand, we observed a peculiar phenomenon in the SAT time series where the SAT values have sharply decreased to more than 4 K from the corresponding LB on January 23, 2020 (Fig. 2a). The spatial anomaly maps of the SAT suggest a similar drop of 4 K explicitly over the epicenter, compared to the rest of the analyzed days (Fig. 5). This decrease of the air temperature simultaneously with the growth of the ACP is observed to be a very rare effect (Fig. 2). It could be explained in the following way: probably the sharp drop of relative humidity led to the drop of the air pressure according to Dalton's law of partial pressures because of the drop of the water vapor partial pressure. On days 22–23 January, the cold was approaching from the northwest direction, and a

sharp depression over the impending EQ's epicenter sucked down the tongue of the cold air in the preparation area of the M 7.7 Jamaica EQ, which led to the temperature drop.

Such a drop in relative humidity (Fig. 3a) and increased ACP (Fig. 2b), resulting in the condensation of water vapor and latent heat release before the EQs, are the main drivers of the air ionization. In general, latent heat increases due to an increase in evaporation, which is a result of an increased amount of water vapor around the EQ epicenter (Mansouri Daneshvar et al., 2014). Figure 3a represents the time series for the total column water vapor during the whole month of January 2020. We observed a significant increase in column water vapor of about $\sim 4 \text{ kg/m}^3$ from the corresponding UB on January 23, 2020. It is worth noting that $\sim 2494 \text{ J}$ of heat releases during condensation of only 1 g of water vapor from each cubic meter of air that further results in about a 6.7% drop of relative humidity, which has been confirmed by satellite-based

Figure 5

Spatial anomaly maps of surface air temperature from NOAA between January 19 and 30, 2020, where white star represents the epicenter of Jamaica EQ. The dashed-red square exhibits anomalous days

measurements (Pulinets & Ouzounov, 2018). Additionally, radon emitted α -particles carry average energy of about 6 MeV and can generate up to 4.5×10^5 ions-electron pair. In an experimental study conducted by Wilding and Harrison (2005), it was observed that a single ion may carry a hundred water molecules. Hence, the increased amount of water vapor will provide a large number of water molecules to radon ions, and as a consequence, an increase in latent heat. Another atmospheric phenomenon related to the increased radon is the atmospheric pressure. Figure 6 delineates a peculiar decrease of 14 millibars (mb) in air pressure on January 23, 2020 (5 days before the EQ), which is another sign of increased radon activity over the M 7.7 EQ preparation zone. On the other hand, the radon-induced ionization exists at different levels in the atmosphere, the combined energy released by each α -particle will be finally converted to heat at the top of the atmosphere, which can be monitored by the satellite in the form of OLR. Figure 7 represents an enormous

increase of about 30 W/m^2 in the OLR values on January 23, 2020, right over and around the epicenter of M 7.7 Jamaica EQ, which provides another indication of the seismically induced atmospheric environment.

Furthermore, the air ionization, produced by increased radon emanations and column water vapor, is the main source of ions production at the atmospheric Planetary Boundary Layer (PBL). The air ionization further provides increased air conductivity at PBL by formulating large ion clusters having a size of aerosols size particles that lead to a generation of the steady steep electric field over the entire EQ preparation area, which is responsible for ionospheric variabilities (Pulinets & Davidenko, 2014). Hence, in order to testify to an agreement with atmospheric variations observed on January 23, 2020, we used bi-hourly GIM-TEC maps for that particular day to study the ionospheric effects engendered by gigantic M 7.7 Jamaican tremblor. Figure 8 represents spatial GIM-TEC anomaly maps on January 23, 2020, where

Figure 6

Air pressure anomaly maps from NOAA between January 19 and 30, 2020, at an altitude of 9 km above mean sea level. The epicenter of the Jamaican 7.7 EQ is represented by a white star, and the anomalous day is denoted by a dashed-red square

one can observe that the ionospheric anomalies lasted for 6 h (LT = 13–19 (– 5 UT)). A maximum deviation of 4 TECU can be observed during these anomalous hours around the epicentral area. The demonstration of these anomalies conjectures their specificity concerning the region. Even though these fluctuations are local but the existence of geomagnetic storm catastrophe may mask these ionospheric anomalies. Figure 9 describes the geomagnetic conditions that indicate all quiet space weather on January 23, 2020. It can be observed that the Kp index remained less than 3, similarly, SYMH recorded greater than – 15 nT, and F10.7 remained less than 70 SFU on January 23, 2020. These results manifest that the ionospheric depletions observed over M 7.7 epicenter, are not contributed by geomagnetic activity.

Moreover, the GIMs demonstrate the observed TEC variations at the altitude of the fixed-height thin layer that is generally defined as 350–450 km. Thus, to further explore the lower ionospheric variations, the vertical ionospheric profiles from F7/C2 were analyzed between LT = 13–19 (– 5 UT). The

selection of this specific period was subjected to the anomalous hours observed in the GIM-TEC maps. A considerable decrement of ~ 10 TECU from the corresponding median can be observed in ionospheric TEC profiles on January 23, 2020, between an altitude of 60–400 km, as shown in Fig. 10. Additionally, the atmospheric profiles, including SAT and air pressure, have shown consistency with our spatial observation from NOAA-PSL, as they exhibited significant diminutions from their corresponding medians at different atmospheric altitudes, exploiting LAI interactions (Fig. 10). We further conducted a brief analysis to explore TEC behavior at the lower ionosphere by constructing the spatial F7/C2 TEC maps at seven 25 km altitude intervals from 75 to 225 km, right above the epicenter. A co-located chained synchronous reduction was observed in TEC values, explicitly, over a small region above the epicenter between LT = 13–19 (– 5 UT), as represented by Fig. 11. Between 75 and 125 km, the TEC values are extremely reduced (less than 50 TECU), while between 150 and 175 km the TEC values seemed to be diluted but remained significant

Figure 7

Spatial anomaly maps of OLR between January 20 and 28, 2020, at top of the atmosphere (altitude = 12 km (above mean sea level)). The dashed-red rectangle shows the anomalous day and the white star represents the epicenter

compared to surroundings, whereas between 200 and 225 km the significance of TEC reductions again increased. It can be observed that the existence of these TEC anomalies is extremely local and ornately persuaded by the seismogenic electric field generated from air ionization produced from the increased radon activity at the PBL.

After meticulous analysis, these results incite a LAIC phenomenon before M 7.7 that could be considered as potential short-term precursors. In Fig. 11, all the results have been summarized into a single framework that explicates the formation of seismically induced anomalies from the surface to the ionosphere, at different altitude levels, divulging the LAIC. Our results confirm the LAIC phenomenon proposed by Pulinets et al. (2015) and provide deep insight into earth-atmosphere processes leading to ionospheric changes, where the time and space synchronization of all parameters on 23 January demonstrates the system proximity to the critical point.

4. Discussion

With respect to the perception of the EQ preparation area (Dobrovolsky et al., 1979) for M 7.7 Jamaica EQ, which has the spread over 0–36° N in latitude and 58–98° W in longitudes, the whole Caribbean sea, and associated islands have experienced the structural deformation, so the radon enhancements might have experienced throughout the region. Although due to data limitations, the direct radon measurements are not presented in this study. Nevertheless, the ACP can serve as a proxy of radon activity (Pulinets et al., 2015). Its temporal evolution for January 2020 in the epicenter of the Jamaica EQ demonstrates the sharp increase within the time interval of 22–25 January that can be interpreted as increased radon activity. It is quite natural that our results show strong evidence of air ionization production due to increased radon emanations and atmospheric coupling that further induced ionospheric variabilities. The enhanced radon excretions

Figure 8

The ionospheric GIM-TEC maps from the International GNSS Service (IGS) on January 23, 2020 (5 days before EQ), in the form of difference TEC (dTEC) that were obtained by subtracting the observed day values by the mean of the previous 30-days. The white star represents the location of the M 7.7 tremor and the dashed-red circle denotes the location of the anomalies

serve as the condensation of water droplets and consequently, latent heat of vaporization produced. This condensation takes place due to a drop in relative humidity at any level (mid-troposphere) with an appropriate range.

In our analysis, we have found strong evidence of the air ionization production in the form of simultaneously increasing ACP and total column water vapor and decreasing relative humidity and air temperature over the epicenter of the Jamaica EQ that led to the production of OLR anomalies and a drop in the air pressure on January 23, 2020. Since these are the climatological parameters, therefore, we have analyzed the 5-years mean of these parameters between the years 2015–2019, where no significant seismicity was present, to ensure that the observed atmospheric anomalies are unique and not periodic. To make a confutation analysis, we have investigated the datasets of the SAT, relative humidity, and total column water vapor for the year 2019 in January (Figs. 2 and 3). From Fig. 2, we can see that the SAT time series

for the year 2019 exhibit very normal behavior with respect to the 5-years mean and the corresponding UB/LB without showing any abnormality throughout the month. Similarly, the time series of the column water vapor for the year 2019 also demonstrates the usual posture without any abrupt enhancement compared to the UB and 5-years mean (Fig. 3a). Moreover, the 2019 year's temporal variations of relative humidity have exhibited normal distribution with respect to 5-year mean and LB except on January 31, 2019, where we can observe an abrupt decrease (Fig. 3b), but interestingly enough, we did not find any simultaneous variations neither in the form of increased water vapor nor in air temperature on this particular day (Figs. 2 and 3). It means that this decrease in the relative humidity might be a climatological effect that didn't affect the water vapor and air temperature. It is noteworthy that the variations in the air temperature and water vapor are the ultimate source of the condensation process, which strengthens our findings before the M 7.7

Figure 9

Solar and geomagnetic indices with a temporal resolution of 5 min: the top three panels hold solar index F10.7, SYMH (a high-resolution form of Dst index), and Kp index, between January 20 and 28, 2020. While the lower two panels carry the 24-h variations of SYMH and Kp indices for January 23, 2020, where the x-axis contains UT hours. The yellow highlighted area represents an anomalous period

Jamaica seismic event. This confutation analysis suggests that the simultaneous variations in relative humidity, SAT, and total column water vapor, observed on January 23, 2020, are peerlessly unique that demonstrates the production of air ionization over the seismic preparation zone.

According to Pulinets and Ouzounov (2018), a drop in relative humidity due to radon emissions, and increased column water vapor are mainly responsible for the condensation process, and as a consequence, latent heat releases. Furthermore, according to İnan et al. (2008), the rate of radon enhancements due to seismic activity may attain a value of $\sim 2000 \text{ Bq/m}^3$. Whereas, the radon ion production rate is $\sim 6 \times 10^8 \text{ s}^{-1}$ and latent heat constant is approximately

equal to $40.68 \times 10^3 \text{ J/mol}$. Hence, heat energy of about 16 W/m^2 should be released for given radon measurement and associated formation of ions having a size of $1 \mu\text{m}$ (Pulinets et al., 2015), which agrees with OLR measurements of 20 W/m^2 registered by (Ouzounov et al., 2007). Similarly, the OLR measurements recorded in our study exceeds 30 W/m^2 (Fig. 7), which also provides strong evidence of seismically induced radon before M 7.7 EQ. Furthermore, air ionization at PBL is largely responsible for changes in the Global Electric Circuit (GEC), which is further responsible for atmospheric-ionospheric coupling. The pleonastic conception of GEC is discussed by Pulinets and Davidenko (2014) and Pulinets et al. (2015). They explained that the main

Figure 10

Ionospheric and atmospheric parameters extracted from F7/C2 satellites. **a** Ionospheric TEC from GNSS G-28 at LT = 14:58. **b** Ionospheric TEC from GNSS G-07 at LT = 17. **c** Air temperature at surface. **d** Air Pressure at 9 km. The solid-red line represents observed data on January 23, 2020, whereas the dashed-dotted-blue line represents the median values calculated from the median of 10 days before the observed day. The other geographical plots denote the ground track followed by these two satellites, around the epicenter, where the solid red line represents January 23, 2020, and the other blue lines represent the ground tracks of median days. The analysis level of TEC profiles was truncated to an altitude between 60 and 400 km

forces that drive the GEC are thunderstorms and large radioactive structures (such as radon ionization) that produce vertical electric current over the planetary boundary. The PBL is largely dependent on variable plate boundary resistance, once the resistance is changed, the current flow between the atmosphere and ionosphere will also change. Moreover, the variations in the ionosphere are largely dependent on PBL, a sharp increase in radon measurements may lead to ionospheric depletions causing an increase in atmospheric boundary conductivity. In our case, we also recorded ionospheric depletions of about 4 TECU in GIM-TEC (Fig. 8) that demonstrate radon

enhancements and consequent LAIC phenomenon. Figure 11 portrays an overview of the LAIC phenomenon observed before large Jamaica EQ, where a chained synchronous anomaly pattern can be observed. Similar findings were registered by Giuliani et al. (2009), where a radon anomaly followed by anomalies in SAT and OLR, and further in the ionospheric TEC was detected.

The exhibition of concomitant anomalies from the surface to the ionosphere indicates an abrupt increase in radon emissions lead by tectonic activity that could be considered as potential EQ precursors before M 7.7 Jamaica EQ.

5. Conclusion

This paper presents the anomalous conditions observed before Jamaica EQ of January 28, 2020, in pursuit of a possible precursory phenomenon. We observed a reduction of 25% in relative humidity, 14 mb in air pressure, and 4 K in the SAT, which provides evidence of increased radon emanations about five days before the EQ. The simultaneous variations in the form of a drop in relative humidity, SAT, and increased total column water vapor, as well as dropping air pressure and increasing OLR, indicate the production of air ionization through the condensation of water vapor in the atmosphere. On the other hand, our confutation analysis, based on the datasets of the previous 5 years in the same month and region, confirmed that the observed variations are categorically unique and not periodic in the absence of significant seismicity periods. Moreover, we observed an ionospheric anomaly in the form of GIM-TEC and F7/C2 TEC profiles as a result of the air ionization production over the atmospheric boundary layer that exhibits a LAIC phenomenon. An overview of the LAIC phenomenon and a summary of these results are presented in Fig. 11. Even though

our results evidenced the occurrence of seismic ionospheric precursors, but still we suggest that due to the diverse nature of the ionospheric environment, as it is very vulnerable to other sources such as traveling ionospheric disturbances and solar activity, etc., it will be very arduous and complicated to find an EQ precursor in the ionosphere during the presence of high geomagnetic conditions and solar activities.

The combined approach used in this study (from the ground to the ionosphere) has never been used previously by any researcher. We recommend more precursory analysis with a similar approach to further explore the LAIC phenomenon. We believe that our multi-precursory analysis at different altitude levels is another conferment to comprehend the LAIC phenomenon and future EQ forecasting.

Acknowledgements

The authors are extremely thankful to Editor-in-Chief Alexander Rabinovich and two anonymous referees for their valuable comments and suggestions in improving the manuscript quality. We are indebted

to the NOAA-PSL community for providing the atmospheric datasets, NASA's Global Modelling and Assimilation Office for providing the datasets of total column water vapor, relative humidity, and SAT, the IGS network for providing the GIM-TEC maps, and Taiwan's National Space Organization (NSPO) / University Corporation for Atmospheric Research (UCAR) of the U.S. for F7/C2 datasets. We are also obliged to the United States Geological Survey (USGS) for providing information about the EQ and OMNIWEB NASA for providing the space-weather indices.

Terms and Conditions

Springer Nature journal content, brought to you courtesy of Springer Nature Customer Service Center GmbH (“Springer Nature”). Springer Nature supports a reasonable amount of sharing of research papers by authors, subscribers and authorised users (“Users”), for small-scale personal, non-commercial use provided that all copyright, trade and service marks and other proprietary notices are maintained. By accessing, sharing, receiving or otherwise using the Springer Nature journal content you agree to these terms of use (“Terms”). For these purposes, Springer Nature considers academic use (by researchers and students) to be non-commercial.

These Terms are supplementary and will apply in addition to any applicable website terms and conditions, a relevant site licence or a personal subscription. These Terms will prevail over any conflict or ambiguity with regards to the relevant terms, a site licence or a personal subscription (to the extent of the conflict or ambiguity only). For Creative Commons-licensed articles, the terms of the Creative Commons license used will apply.

We collect and use personal data to provide access to the Springer Nature journal content. We may also use these personal data internally within ResearchGate and Springer Nature and as agreed share it, in an anonymised way, for purposes of tracking, analysis and reporting. We will not otherwise disclose your personal data outside the ResearchGate or the Springer Nature group of companies unless we have your permission as detailed in the Privacy Policy.

While Users may use the Springer Nature journal content for small scale, personal non-commercial use, it is important to note that Users may not:

1. use such content for the purpose of providing other users with access on a regular or large scale basis or as a means to circumvent access control;
2. use such content where to do so would be considered a criminal or statutory offence in any jurisdiction, or gives rise to civil liability, or is otherwise unlawful;
3. falsely or misleadingly imply or suggest endorsement, approval, sponsorship, or association unless explicitly agreed to by Springer Nature in writing;
4. use bots or other automated methods to access the content or redirect messages
5. override any security feature or exclusionary protocol; or
6. share the content in order to create substitute for Springer Nature products or services or a systematic database of Springer Nature journal content.

In line with the restriction against commercial use, Springer Nature does not permit the creation of a product or service that creates revenue, royalties, rent or income from our content or its inclusion as part of a paid for service or for other commercial gain. Springer Nature journal content cannot be used for inter-library loans and librarians may not upload Springer Nature journal content on a large scale into their, or any other, institutional repository.

These terms of use are reviewed regularly and may be amended at any time. Springer Nature is not obligated to publish any information or content on this website and may remove it or features or functionality at our sole discretion, at any time with or without notice. Springer Nature may revoke this licence to you at any time and remove access to any copies of the Springer Nature journal content which have been saved.

To the fullest extent permitted by law, Springer Nature makes no warranties, representations or guarantees to Users, either express or implied with respect to the Springer nature journal content and all parties disclaim and waive any implied warranties or warranties imposed by law, including merchantability or fitness for any particular purpose.

Please note that these rights do not automatically extend to content, data or other material published by Springer Nature that may be licensed from third parties.

If you would like to use or distribute our Springer Nature journal content to a wider audience or on a regular basis or in any other manner not expressly permitted by these Terms, please contact Springer Nature at
