Abstract

Air pollution is a public health issue and the toxicity of ambient particulate matter (PM) is well-recognized. Although it does not mostly contribute to the total mass of PM, increasing evidence indicates that the ultrafine fraction has generally a greater toxicity than the others do. A better knowledge of the underlying mechanisms involved in the pathological disorders related to nanoparticles (NPs) remains essential. Hence, the goal of this study was to determine better whether the exposure to a relatively low dose of well-characterized iron-rich NPs (Fe-NPs) might alter some critical toxicological endpoints in a relevant primary culture model of human bronchial epithelial cells (HBECS). We sought to use Fe-NPs representative of those frequently found in the industrial smokes of metallurgical industries. After having noticed the effective internalization of Fe-NPs, oxidative, inflammatory, DNA repair, and apoptotic endpoints were investigated within HBECS, mainly through transcriptional screening. Taken together, these results revealed that, despite it only produced relatively low levels of reactive oxygen species without any significant oxidative damage, low-dose Fe-NPs quickly significantly deregulated the transcription of some target genes closely involved in the proinflammatory response. Although this inflammatory process seemed to stay under control over time in case of this acute scenario of exposure, the future study of its evolution after a scenario of repeated exposure could be very interesting to evaluate the toxicity of Fe-NPs better.

KEYWORDS

gene expression profiling, human bronchial epithelial cells, inflammation, iron nanoparticles, oxidative stress, physicochemical characterization

1 | INTRODUCTION

Air pollution still constitutes the major threat to human health, whereas the adverse impacts and the underlying mechanisms of air pollution-derived particulate matter (PM) are not clearly defined (Beelen et al., 2015; Hamra et al., 2014; Jerrett et al., 2017; Raaschou-Nielsen et al., 2016). PM is a mixture of solid and liquid tiny particles of different origins, sizes and compositions. Various classifications and terminologies have been used to define particle size

ranges (Terzano, Di Stefano, Conti, Graziani, & Petroianni, 2010). Generally, particles are divided into three groups, namely, coarse, fine and ultrafine particles (UFP) with aerodynamic diameters within a range between 2.5 and 10 μm ($\text{PM}_{10-2.5}$), <2.5 μm ($\text{PM}_{2.5}$) and <0.1 μm ($\text{PM}_{0.1}$), respectively (Chen et al., 2016). Ambient PM is most often characterized by the content of PM_{10} and $\text{PM}_{2.5}$, as their concentrations are limited by the air quality guidelines of the World Health Organization (20 $\mu\text{g}/\text{m}^3$ annual mean and 50 $\mu\text{g}/\text{m}^3$ 24-hour mean for PM_{10} , and 10 $\mu\text{g}/\text{m}^3$ annual mean and 25 $\mu\text{g}/\text{m}^3$ 24-hour

mean for $PM_{2.5}$). The association of pulmonary and cardiovascular adverse health effects with PM_{10} or $PM_{2.5}$ ambient levels has been already well-described. Although they do not contribute substantially to total mass of particles, increasing evidence indicates that UFP, particularly those that originated from human activities, may have greater impact on human health than the other larger sized fractions (Kornberg et al., 2017). In contrast to UFP, which are derived from both natural and anthropogenic sources, nanoparticles (NPs), commonly defined as particles having at least one dimension <100 nm, are prepared deliberately by humans at the nanoscale. Consequently, they exhibit properties that provide technological advantages compared with the bulk form of the same material (Stone et al., 2017). The health effects induced by engineered NPs are similar to those caused by UFP, as inhalation is the most probable and easiest route for nanosized particles to enter into the human body (Stone et al., 2017). The research findings of NPs in nanotoxicology prove that they behave differently from larger inhalable particles, and their chemical constituents, which are nontoxic at the micrometer scale, will become toxic at the nanometer scale (Kornberg et al., 2017). To achieve engineering for safety goals, it is also urgently needed to understand the toxicity of NPs better themselves and recognize that toxicological evaluation is only one part of an overall risk assessment process. However, it is impossible to determine safer exposure levels and safer material designs without having first a better knowledge of dose-specific toxicological effects.

The risk of exposure to NPs is particularly high for people working within the production sites of engineered NPs. NPs made by transition metals are widely used in technology and some of them are known to induce both pro-oxidative and proinflammatory activities (Andersen et al., 2011; Gustafsson, Lindstedt, Elfsmark, & Bucht, 2011; Jerrett et al., 2017). For instance, fine/micron-sized iron-rich PM (Fe-PM) is incidentally released from a number of industrial processes, including iron ore mining, steel processing, welding and pyrite production (Kornberg et al., 2017). Moreover, Fe-NPs are naturally present in the outdoor atmospheres because they may be emitted from building materials and vehicles, such as cars and train brakes (Gasser et al., 2009; Wilkinson et al., 2012). The use of more efficient air filters in industries allowed to retain the fine but not the ultrafine fraction of emitted PM, the latest still representing an area of toxicology of emerging concern (Stone et al., 2017). During the exposure, NPs mainly penetrate into the body by inhalation, and, after deposition within the lungs, can provoke some severe injuries (e.g., inflammation, bronchial hyper-reactivity, tissue remodeling) and even contaminate the bloodstream (Brandenberger et al., 2010; Oberdörster et al., 2004; Patil et al., 2012; Petitot et al., 2013; Suliman et al., 2015). Indeed, the internalization of different types of NPs into various human lung cell models has already been well-reported (Stone et al., 2017). There is also a number of underlying mechanisms by which NPs may impair cell homeostasis, including the occurrence of oxidative and inflammatory responses (Miller et al., 2013; Nel, Xia, Mädler, & Li, 2006; Stone et al., 2017). The ability of NPs to induce an overproduction of reactive oxygen species (ROS), either intrinsically or via different cell sources, has been well documented and is frequently associated with

other toxic effects (Stone et al., 2017). Although the mechanisms underlying Fe-NP-induced toxicity are still poorly understood, most researchers suggested they are largely due to Fe-induced or catalyzed ROS production (Ghio, Dailey, Richards, & Jang, 2009). Accordingly, Fe-PM, as wüstite (FeO) and hematite (Fe_2O_3), has already been shown as inducing redox and inflammatory responses in a set of in vitro and in vivo studies (Garçon et al., 2000; Garçon et al., 2001a, 2001b, 2004a, 2004b). More recent studies supported similar results for Fe-NPs (Bhattacharya et al., 2012; Donaldson et al., 2005; Eom & Choi, 2009, 2011; Keenan, Goth-Goldstein, Lucas, & Sedlak, 2009; Kim, Kim, Lee, Oh, & Chung, 2011). However, these effects are likely to be related to multiple physicochemical characteristics of Fe-NPs and may include other underlying mechanisms of toxicity such as direct physical NP-cell interaction and receptor-mediated activation of specific signaling pathways (Thomassen et al., 2011).

The better knowledge of the underlying mechanisms closely involved in the pathogenesis of lung disorders related to NPs remains essential. Hence, we sought to use an original primary culture model of human bronchial epithelial cells (HBECs) to test the toxicity of a relatively low dose of well-characterized Fe-NPs, representative of those encountered in the industrial smokes of metallurgical industries (Canivet, Denayer, Champion, Cenedese, & Dubot, 2014). After having verified the effective internalization of Fe-NPs into HBECs, oxidative, inflammatory, DNA repair and apoptotic endpoints were also investigated.

2 | MATERIALS AND METHODS

2.1 | Chemicals

All the culture reagents were provided by LONZA. Sigma-Aldrich provided all the chemical reagents and monoclonal pan-cytokeratin antibody (Clone PCK-26). Promega provided CellTiter-Glo® luminescent cell viability. ThermoFisher Scientific provided Alexa Fluor™ 488 conjugated goat polyclonal antimouse antibody, SlowFade Gold Antifade reagent containing DAPI, 6-carboxy-2',7'-dichlorodihydrofluorescein diacetate (carboxy- H_2DCFDA), Pierce™ BCA protein assay kits, and all the reagents for molecular biology. Qiagen provided RNeasy mini Kits. Merck-Millipore provided periodic acid-Schiff (PAS) staining kit and MU5AC antibody (mouse monoclonal MAB2011; Clone CLH2).

2.2 | Iron nanoparticle synthesis and physicochemical characterization

Metallic iron nanocrystals were produced using a cryogenic melting gas condensation technique as described by Champion and Bigot (1996). Briefly, to avoid contamination through reaction with a crucible, the metal was heated in a radiofrequency levitation furnace. The analytical methods used to determine the physicochemical characteristics of Fe-NPs have been published elsewhere (Canivet et al., 2014). Briefly, the shape and the size of Fe-NPs, at their pristine state or after their suspension in Hanks' balanced salt solution (HBSS)

or bronchial epithelial cell growth medium, with or with sonication, were determined by scanning electron microscopy (LEO 1530; Zeiss). Their surface charge, chemical composition and specific surface area were determined by dynamic light scattering (Zetasizer II; Malvern Instruments), X-ray photoelectron spectroscopy (K-ALPHA; ThermoScientific), and Brunauer, Emmet and Teller (BET) method by nitrogen adsorption (Micromeritics Type ASAP 2010), respectively.

2.3 | Human bronchial epithelial cell culture and characterization

HBECs were derived from healthy peripheral bronchial tissues of patients ($n = 3$) undergoing surgery for lung carcinoma, as published elsewhere (Courcot et al., 2012). After surgical resection, macroscopically healthy areas of lobar bronchi were immediately immersed in Dulbecco's modified Eagle's medium supplemented with 1% (v/v) penicillin-streptomycin and 2% (v/v) fungizone, and then stored at 4°C until used. Bronchial segments were rinsed twice with ice-cold phosphate-buffered saline (PBS) and processed for mucosa isolation. Small pieces of bronchial mucosa, approximately 2 mm², were used as a source of primary cells. They were placed in Petri dishes, pre-coated with rat tail type I collagen at 0.03 mg/mL for 30 minutes at 37°C, in the presence of 5 mL of a serum-free medium (bronchial epithelial cell growth medium; Lonza) supplemented with 1% (v/v) penicillin-streptomycin and 2% (v/v) amphotericin B. After an adherence period of 24 hours at 37°C and 5% CO₂, 5 mL of supplemented culture medium were added and, thereafter, changed every 2-3 days until epithelial cells grown from bronchial explants reached almost full confluence. After trypsinization, HBECs were gathered, reseeded in six-well plates, 96-wells plates or LabTeck® chamber Slide™ Systems, precoated with rat tail type I collagen at 0.03 mg/mL for 30 minutes at 37°C, and cultured until confluency.

HBECs ground on LabTeck® chamber Slide™ Systems were fixed with 1% (v/v) paraformaldehyde for 3 minutes at 37°C and methanol for 5 minutes at −20°C. Mucus secretion was identified by PAS reaction using the standard protocol recommended by the manufacturer (PAS staining kit; Merck-Millipore). HBECs were mounted using the Eukitt® quick-hardening mounting medium. For immunofluorescence labeling, HBECs were permeabilized for 3 minutes with PBS containing 0.2% (v/v) Triton X-100 and rinsed three times for 5 minutes with PBS. They were incubated for 1 hour at 37°C with primary antibodies diluted in 3% (v/v) bovine serum albumin, 0.05% (v/v) Tween and 0.08% (v/v) sodium azide in PBS. MU5AC antibody (mouse monoclonal MAB2011; Clone CLH2; Merck-Millipore) and monoclonal pancytokeratin antibody (Clone PCK-26; Sigma-Aldrich) were respectively diluted at 1/250 and 1/100. After three 5-minute washes in PBS, HBECs were incubated for 30 minutes at 37°C with a goat polyclonal antimouse antibody, Alexa Fluor™ 488 conjugate (ThermoFisher Scientific) diluted at 1/400 in 3% (v/v) bovine serum albumin, 0.05% (v/v) Tween and 0.08% (v/v) sodium azide in PBS (Leclercq et al., 2016; Sotty et al., 2019). After three 5-minute washes in PBS, HBECs were mounted with the SlowFade Gold Antifade reagent

containing DAPI (Life Technologies) and images were acquired on an EVOS™ FL Cell Imaging System (Life Technologies).

2.4 | Human bronchial epithelial cell exposure to iron nanoparticles

Just before cell exposure, culture media were renewed to eliminate death cells, and Fe-NPs were extemporaneously suspended in sterile HBSS (ThermoFisher Scientific) and ultrasonicated (Deltasonic; Somatherm; frequency: 28 kHz; power source: 120 W) for 5 minutes before their use. According to Kaur et al. (2017), the effective acoustic power delivered to the dispersion in the ultrasonic bath was calculated to be 0.193 W. CellTiter-Glo® luminescent cell viability assay was carried out in HBECs exposed to increasing concentrations of Fe-NPs from 0 to 300 µg/cm² for 24 hours at 37°C and 5% CO₂, as recommended by the manufacturer's instructions (Promega). This assay system used the properties of a proprietary thermostable luciferase to enable reaction conditions that generate a stable "glow-type" luminescent signal. The mono-oxygenation of luciferin was catalyzed by luciferase in the presence of Mg²⁺, ATP and molecular oxygen, and resulted in the emission of light, directly linked to the ATP concentration and the number of living cells. Accordingly, for the further study of the other toxicological endpoints, HBECs were thereafter exposed in triplicate to a final concentration of 2 µg/cm² (or 9.5 µg/mL) of Fe-NPs for 6, 24 and 48 hours.

2.5 | Human bronchial epithelial cell observations by transmission electron microscopy

HBECs exposed for 24 hours at 37°C and 5% CO₂ to Fe-NPs at 2 µg/cm² (or 9.5 µg/mL) were washed twice with PBS, fixed in 0.5% (v/v) paraformaldehyde- and 2% (v/v) glutaraldehyde-containing PBS for 20 minutes at room temperature, and then overnight at 4°C after renewing the fixative solution (Leclercq et al., 2018; Sotty et al., 2019, 2020). After three washes with a solution of 0.22 M sucrose in PBS for 10 minutes, HBECs were post-fixed with 1% (m/v) OsO₄ in PBS for 2 hours at room temperature. Fixed samples were thereafter dehydrated in a series of graded alcohols and embedded in Epon resin. Ultrathin sections (50-90 nm) were cut with an ultramicrotome (Reichert Ultracut E), stained with uranyl acetate and lead citrate, and examined with a Zeiss EM902 transmission electron microscope at 80 kV equipped with the Orius camera interface (Carl Zeiss France SAS). Numerical images were acquired with Gatan Microscopy Suite® software.

2.6 | Reactive oxygen species production and oxidative damage within human bronchial epithelial cells

To study production of ROS, HBECs were incubated with 20 µM carboxy-H₂DCFDA in HBSS (ThermoFisher Scientific) for 1 hour at 37°C and 5% CO₂. Thereafter, HBECs were washed with PBS and exposed to Fe-NPs at 2 µg/cm² (or 9.5 µg/mL), 20 µM phorbol ester myristate (Sigma) as positive controls, or 40 µM *N*-acetylcysteine

(ThermoFisher Scientific) as negative controls. Fluorescence (λ_{ex} : 492–495 nm; λ_{em} : 517–527 nm) was monitored at 37°C every 10 minutes for 3 hours with the GloMax®-Multi Detection System (Promega). Malondialdehyde (MDA) concentrations were determined in HBECs lysed with 0.1% (m/v) butylated hydroxytoluene ethanolic solution using high-performance liquid chromatography with fluorescence detection, as published by Garçon et al. (2006). Glutathione status (i.e., ratio between oxidized and reduced forms: [GSSG]/[GSH]) was determined in HBECs lysed with 10% (v/v) cold metaphosphoric acid using high-performance liquid chromatography with fluorescence detection, as published elsewhere (Leclercq et al., 2016, 2017). The total protein quantification was determined using the Pierce™ BCA Protein Assay Kit (ThermoFisher Scientific) according to the manufacturer's recommendations.

2.7 | Regulation of gene expression within human bronchial epithelial cells

Total RNA was extracted from HBECs with the miRNeasy Mini Kit™ (Qiagen) according to the manufacturer's instructions. The yield of the extracted RNA was determined by measuring the optical density at 260 nm with the BioSpec nanospectrophotometer (Shimadzu). After reverse transcription of 1 µg of total RNA in single-stranded cDNA using the High Capacity cDNA Reverse Transcription Kit (ThermoFisher Scientific), gene expression relative quantitation was carried out using custom TaqMan™ Low Density Arrays, a 7900HT Real-Time polymerase chain reaction (PCR) System (ThermoFisher Scientific), and the Expression Suite Software (ThermoFisher Scientific). The set of selected genes comprised target genes encoding proteins involved in oxidative stress regulation (43), inflammatory process (223), DNA repair and apoptosis regulation (72), and other functions (42, including 15 mucin genes) (see Supporting Information). The mRNA expression levels of the 10 genes exhibiting the highest differential expressions after Fe-NP exposure were analyzed in HBECs derived from three independent donors, using reverse transcription-quantitative PCR. PCR amplifications were conducted on the Step one plus thermocycler using 50 ng of reverse transcription products, TaqMan Gene Expression Master Mix (2x) and specific TaqMan Gene Expression Assays (20x), according to the protocol supplied by the manufacturer (ThermoFisher Scientific). The analysis of gene expression was realized using the RQ Manager 1.3 software (ThermoFisher Scientific).

2.8 | Statistical analysis

Normality and equality of variances were checked for each data set. Data were presented as means and standard deviations of triplicate. Each experimental value was compared with that of the corresponding negative control at each time point. When the normality and the equality of variance were checked, one-way analysis of variance was used to examine the difference between Fe-NP exposed- and negative control HBECs. Then, a Dunnett's post hoc

test was carried out for pairwise difference, using negative control HBECs. When normality was skewed, a Kruskal-Wallis test was performed (followed by Dunnett's post hoc test). The level of statistical significance was set at $P < .05$. Analyses were performed with SigmaStat® 2.03 software (SPSS Inc.).

3 | RESULTS

3.1 | Iron nanoparticle physicochemical characteristics

The physicochemical characterization of the Fe-NPs under study was first performed in their pristine state. As shown in Figure 1A and Table 1, Fe-NPs were associated in bundles but have an individual spherical shape with a diameter in the range of 20.0–80.0 nm. Accordingly, BET measurements realized with N₂ on Fe-NPs gave a specific surface of $21.72 \pm 0.17 \text{ m}^2/\text{g}$. Assuming a density of $7.87 \text{ g}/\text{cm}^3$ for iron, Canivet et al. (2014) estimated a mean diameter of 35.1 nm for the individual spherical Fe-NPs. These Fe-NPs were also representative of industrial smoke emitted by metallurgical industries. They were formed from a metallic iron core with an oxide layer (Fe^{2+} and Fe^{3+}) of 2.1 nm, as revealed by the Fe_{2p} core level. A layer of hydroxide could be shown by deconvolution of the O_{1s} peak. Fe-NPs were free from any impurity. Fe-NPs were magnetic and formed some agglomerates, with an average size of 700 nm. The sonication of Fe-NP solution reduced their average size to 200 nm. Their zeta potential and surface area at their pristine state were -12 mV and $21.72 \text{ m}^2/\text{g}$, respectively. The volume-specific surface area (VSSA), understood as a surface area related to the volume instead of mass, can constitute an additional criterion independent of the size distribution and the density of the nanomaterial. The VSSA of Fe-NPs ($218.27 \text{ m}^2/\text{cm}^3$) allowed us to state that, even agglomerated, they still had their specific reactivity. Thereafter, Fe-NPs were characterized 24 hours after their suspension in HBSS or in supplemented culture medium. Moreover, like Fe-NPs in their pristine state, Fe-NPs suspended in HBSS and in supplemented culture medium formed some agglomerates with average sizes ranging from 600 to 700 nm. Immersion of Fe-NPs in HBSS only slightly increased the oxide thickness from 0.16 to 2.26 nm, whereas the hydroxylation surface was higher from those at their pristine state. While HBSS slightly interplayed toward Fe-NP oxidation at a day scale, on the contrary, supplemented culture medium strongly interact by increasing the iron oxide layer thickness, up to 2.8 nm after 24 hours, and up to 3.1 nm, 24 hours later.

3.2 | Characterization of human bronchial epithelial cells

PAS staining confirmed the capacity of some of the HBECs to secrete mucus (Figure 1B). Both pan-cytokeratin and MUC5AC protein expression, highly characteristic for HBECs, were specifically detected using immunofluorescence labeling of isolated cells (Figure 1C).

FIGURE 1 A, Observation of iron-rich nanoparticles in scanning electronic microscopy (magnification $\times 50\,000$). B, Periodic acid-Schiff of human bronchial epithelial cells; fuchsia color corresponds to polysaccharides (magnification $\times 600$). C, Fluorescence immunostaining of pan cytokeratin and MUC5AC in human bronchial epithelial cells. Nuclei are revealed in blue with DAPI (magnification $\times 400$) [Colour figure can be viewed at wileyonlinelibrary.com]

TABLE 1 Physicochemical characteristics of iron-rich nanoparticles in their pristine state

Shape	Composition	Purity	Surface area (m^2/g)	Size distribution (nm)	Agglomeration (nm)	Zeta potential (mV)	VSSA (m^2/cm^3)
Sphere	Core of metallic iron with an oxide (Fe^{2+} and Fe^{3+}) and hydroxide layer of 2 nm	Free of impurity	21.72	20-80	700 (average of 200 with sonication step)	-12	218.27

3.3 | Iron nanoparticle internalization by human bronchial epithelial cells

Figures 2A and 2B revealed the internalization of Fe-NPs into membrane-bound vesicles, as small aggregates. Fe-NPs entering from

the apical surface could form an endosome, which may cross the cell to the basolateral surface and thereafter fuse with the plasma membrane, thereby releasing Fe-NPs into the extracellular fluid on the basolateral side. Both particle aggregation and agglomeration have been shown to play a major role in the severity of Fe-NP-induced adverse outcomes.

FIGURE 2 A, B, Observations of human bronchial epithelial cells exposed to $2 \mu\text{g}/\text{cm}^2$ of Fe-NPs using transmission electronic microscopy. Confirmation of the presence of Fe-NPs, enclosed in vesicles (red circle), within human bronchial epithelial cells 24 h after their exposure to Fe-NPs. Fe-NPs, iron-rich nanoparticles

3.4 | Cell viability of iron nanoparticle-exposed human bronchial epithelial cells

The viability was reduced in a dose-dependent manner in HBECs 24 hours after their exposure to increasing concentrations of Fe-NPs, ranging from 0 to $300 \mu\text{g}/\text{cm}^2$ (Figure 3). The inhibitory concentration at 10% (i.e., $2 \mu\text{g}/\text{cm}^2$) has been chosen to be further applied to study the other toxicological endpoints.

3.5 | Reactive oxygen species production and oxidative damage in iron nanoparticle-exposed human bronchial epithelial cells

No significant difference of intracellular ROS production was observed between Fe-NP-exposed and negative control HBECs

FIGURE 3 Cell viability, assessed through intracellular adenosine triphosphosphate concentrations of human bronchial epithelial cells exposed for 24 h to increasing concentration of Fe-NPs. Calculated inhibitory concentration at 10% (IC_{10}) corresponded to $2 \mu\text{g}/\text{cm}^2$. Results are expressed as the means $\pm$ SD of three independent experiments conducted in triplicate ($n = 9$). Fe-NPs, iron-rich nanoparticles [Colour figure can be viewed at wileyonlinelibrary.com]

(Figure 4A). Time-dependent continuous increases of intracellular ROS levels were reported for both exposed and negative control HBECs. In this work, to study the possible consequences of Fe-NP-induced ROS production, glutathione status ($[\text{GSSG}]/[\text{GSH}]$) and MDA levels were assessed (Figure 4B and 4C, respectively). However, HBEC exposure to the low-dose Fe-NPs for 6, 24 and 48 hours did not induce any significant modification of glutathione status nor MDA production, despite slight increases.

3.6 | Modulation of gene expression within human bronchial epithelial cells

Venn diagrams showed the expression patterns of differentially regulated genes (DRGs; upregulated: relative quantity [RQ] ≥ 2 or downregulated: $\text{RQ} \leq 0.5$) within Fe-NP-exposed vs. control HBECs (Figure 5A and 5B). Most of them were involved in oxidative stress, inflammation, DNA repair, apoptosis and mucin secretion regulation (see also Table S1; see Supporting Information). Overall, there is a time-dependent decrease of the number of DRGs in Fe-NP-exposed HBECs: after 6 hours, 46 and 32 DRGs were up- and downregulated whereas after 48 hours, only one and four genes were up- and downregulated, respectively. Among the genes deregulated after 6 and 24 hours of exposure: nine genes were upregulated (i.e., *CXCR4*, interleukin (*IL*)13RA2, *MMP1*, *IL24*, *IL17D*, *FGFR1*, *MUC13*, *IL18*, *IL1R2*) and eight genes were downregulated (i.e., *TNFSF10*, *CCR10*, *TLR1*, *TLR3*, *IL7*, *TLR6*, *TNFSF11*, *CXCR2*). Then, after 6 and 48 hours of exposure, three genes were upregulated (i.e., *FGF1*, *LTA*, *NOS3*) and only four genes downregulated (i.e., *CXCL10*, *BAX*, *IL27*, *GPR156*). In addition, as shown in Figure S1 and Table S1 (see Supporting Information), among all the DRGs, 55 target DRGs were highly up- or downregulated as they displayed at least

FIGURE 4 A, Intracellular ROS production in HBECs exposed to $2 \mu\text{g}/\text{cm}^2$ of Fe-NPs. HBECs incubated with 40 mM *N*-acetylcysteine or 20 μM phorbol ester myristate served as negative and positive controls, respectively. Results are expressed as the mean $\pm$ SD of three independent experiments conducted in triplicate ($n = 9$). Kruskal-Wallis test with Dunnett's post hoc test with $t = 5$ min as reference to see the evolution over time ($*P < .05$). B, C, Glutathione status (i.e., ratio between [GSSG]/[GSH] and MDA concentrations ($\mu\text{g}/\text{g}$ of protein) in HBECs exposed to $2 \mu\text{g}/\text{cm}^2$ of Fe-NPs. Values are depicted as mean and SD ($n = 3$). Results are expressed as the means $\pm$ SD of three independent experiments conducted in triplicate ($n = 9$). One-way ANOVA with Dunnett's post hoc test, $*P < .05$. Fe-NPs, iron-rich nanoparticles; [GSSG]/[GSH], ratio between oxidized and reduced form of glutathione; HBECs, human bronchial epithelial cells; MDA, malondialdehyde; ROS, reactive oxygen species; T6, 6 h of exposure; T24, 24 h of exposure; T48, 48 h of exposure [Colour figure can be viewed at wileyonlinelibrary.com]

a fourfold difference in their transcript levels ($\text{RQ} \geq 4$ or $\text{RQ} \leq 0.25$) in Fe-NP-exposed HBECs. Notably, the highest number of highly DRGs was reported 6 hours after exposure to HBECs. Thereafter, among them, a set of 10 DRGs was carefully selected: the eight genes exhibiting the highest changes after Fe-NP exposure (i.e., four upregulated genes: *MMP3*, *IL13RA1*, *MMP1*, *CSF2* and four downregulated genes: *GRP156*, *TNFSF11*, *CCR10*, *CASP5*), and *IL8* and *PTGS2* for their known implication in inflammation processes. The

FIGURE 5 A, Venn diagram representing the expression pattern of upregulated genes ($\text{RQ} > 2$, $P < .05$) in human bronchial epithelial cells exposed to $2 \mu\text{g}/\text{cm}^2$ of iron-rich nanoparticles. B, Venn diagram representing the expression pattern of downregulated genes ($\text{RQ} < 0.5$, $P < .05$) in human bronchial epithelial cells exposed to $2 \mu\text{g}/\text{cm}^2$ of iron-rich nanoparticles (vs. negative controls). RQ, relative quantity; T6, 6 h of exposure; T24, 24 h of exposure; T48, 48 h of exposure [Colour figure can be viewed at wileyonlinelibrary.com]

Fe-NP-induced changes previously reported for all these 10 target genes were confirmed in three independent cell cultures (Table 2). Accordingly, a time-dependent decrease of the number of DRGs was reported in Fe-NP-exposed cells: after 6 hours, six (i.e., *IL8*, *IL13RA2*, *CSF2*, *PTGS2*, *MMP3*, *MMP1*) and one (i.e., *TNFSF11*) DRG were

TABLE 2 Relative quantities of the 10 selected target gene expressions in human bronchial epithelial cells exposed to 2 $\mu\text{g}/\text{cm}^2$ of iron-rich nanoparticles for 6, 24 and 48 h

Gene name	Relative quantity		
	6 h	24 h	48 h
<i>TNFSF11</i>	0.35*	0.50	0.67
<i>CASP5</i>	0.63	0.62	0.67
<i>GPR156</i>	0.80	0.94	0.63
<i>CCR10</i>	0.99	1.64	1.06
<i>IL8</i>	2.73	1.01	1.02
<i>IL13RA2</i>	3.56*	2.42	1.09
<i>CSF2</i>	3.74	2.46	1.66
<i>PTGS2</i>	4.44*	1.57	1.25
<i>MMP3</i>	9.38*	1.39	0.85
<i>MMP1</i>	9.79*	3.90	1.05

respectively up- and downregulated, whereas after 48 hours, no DRGs were reported. After 6 hours, four (i.e., *IL13RA2*, *PTGS2*, *MMP1*, *MMP3*) and one (i.e., *TNFSF11*) DRG were significantly up- and down-regulated, respectively, whereas none were significantly deregulated after 24 and 48 hours.

4 | DISCUSSION

Despite intensive effort during the last decades, there is still a lack of information on NPs in environmental science and human health studies. Interestingly, toxicological studies have shown that nanosized particles possessed quite different physicochemical properties than the fine fraction, such as lower mass, higher reactivity and higher surface area to mass ratio, thereby usually posing more serious adverse effects on human health than larger sized particles (Stone et al., 2017). A thorough knowledge of NPs, including the issues of sources, composition and size distribution is essential for the assessment of the potential health risks and will contribute to the identification of related toxicological effects (Chen et al., 2016). In this study, we investigated the toxicity induced by well-characterized Fe-NPs in HBECs.

The Fe-NPs under study were representative of those emitted by metal industries (Canivet et al., 2014). At their pristine state, Fe-NPs were spherical and ranged from 20 to 80 nm. Assuming a density of 7.87 g/cm^3 for iron, Canivet et al. (2014) estimated a mean diameter of 35.1 nm for the individual spherical Fe-NPs. They were formed from a metallic iron core with an oxide layer (Fe^{2+} and Fe^{3+}) of 2.1 nm, with a layer of hydroxide. Fe-NPs were free from any impurity. Fe-NPs were magnetic and formed some agglomerates, with an average size of 700 nm; their sonication reduced their average size to 200 nm. The VSSA of Fe-NPs (218.27 m^2/cm^3) was allowed to state that, even agglomerated, they still had their specific reactivity. Kreyling, Semmler-Behnke and Chaudhry (2010) noted that NPs with VSSA above 60 m^2/cm^3 are characterized by an average size below 100 nm, thereby indicating a high nanomaterial or nanostructure

content. Thereafter, Fe-NPs were characterized 24 hours after their suspension in HBSS or in supplemented culture medium. Their surface oxidation was in agreement with those reported by Bhattacharya et al. (2009). He et al. (2008) noted that Fe-containing NPs tend to agglomerate when suspended in a low pH solution, the increase of the agglomerate size being directly proportional to their initial size. Kumar et al. (2007) noticed biomolecule adsorption on the surface of Fe-containing NPs, which altered their zeta potential and provoked their agglomeration. While HBSS slightly interplayed toward Fe-NP oxidation at a day scale, on the contrary, supplemented culture medium strongly interact by increasing the iron oxide layer thickness. According to Canivet et al. (2014), immersion of Fe-NPs in HBSS or supplemented culture medium led to the formation of an oxyhydroxide layer containing chlorinated species. The initial passivated surface oxide layer, mainly Fe_2O_3 is thus transformed into a thicker oxyhydroxide layer that has a greater ability to adsorb molecular ions or ionic biomolecules such as proteins or DNA. More soluble iron compounds are formed on the NP surface that could be more easily dissolved after exposition to the intracellular medium. Accordingly, modifications of Fe-NP surface chemistry due to supplemented culture medium can act on cell cytotoxicity both by direct molecular adsorption due to a higher surface affinity to biomolecules or by the induced oxyhydroxide dissolution, which releases toxic iron ions.

Thereafter, to contribute to a better knowledge of the underlying mechanisms involved in Fe-NP toxicity, a relevant primary culture model of HBECs was used. The isolation procedure from healthy peripheral bronchial tissues of patients undergoing surgery for lung carcinomas ensure that they exhibited a phenotype very similar to this observed in vivo (Bérubé, Prytherch, Job, & Hughes, 2010; Boubil et al., 2013; Leclercq et al., 2016, 2017; Leclercq et al., 2018; Pezzulo et al., 2011; Sotty et al., 2019). Accordingly, PAS staining confirmed the capacity of some of them to secrete mucus, whereas, pan-cytokeratin and MUC5AC protein expression, highly characteristic for epithelia and bronchial cells, respectively, were specifically detected using immunofluorescence labeling of HBECs. Bhowmick and Gappa-Fahlenkamp (2016) showed that HBECs displayed the highest similarities with bronchial mucosa in terms of transcript profiling and seemed to be one of the most relevant in vitro models for studying the toxicity of inhaled NPs.

According to Bhattacharya et al. (2009, 2012) and Könczöl et al. (2011), Fe-NPs were internalized into membrane-bound vesicles, as small aggregates. Fe-NPs entering from the apical surface could form an endosome, which may cross the cell to the basolateral surface and fuse with the plasma membrane, thereby releasing Fe-NPs into the extracellular fluid on the basolateral side. Particle aggregation and agglomeration have been shown to play a major role in the severity of Fe-NP-induced adverse outcomes. As mentioned by Kornberg et al. (2017), it is generally accepted that smaller-sized particles are able to induce more toxicity on a per mass basis due to increases of both surface area and particle number. However, if NPs are agglomerated, their adverse outcomes may be different, because they will be recognized by the cells as a larger-sized structure. However, to date, the mechanisms involved in the absorption of Fe-NPs are not well-

identified. Four pathways are described for endocytosis of NPs: caveolar-mediated endocytosis dependent upon clathrin, phagocytosis, micropinocytosis and pinocytosis (Forman & Finch, 2018). Only few studies used HBECs to investigate NP toxicity (Åkerlund et al., 2018; Ekstrand-Hammarström et al., 2013; Herzog et al., 2009; Herzog et al., 2009; Zhang et al., 2011). Most studies have also been conducted using lung cell lines such as immortalized HBECs: BEAS-2B (Ekstrand-Hammarström et al., 2012; Eom & Choi, 2011; Gilbert et al., 2012) and 16HBE cells (Belade et al., 2012; Keenan et al., 2009; Otero-González, Sierra-Alvarez, Boitano, & Field, 2012) or cancer-derived cell lines: A549 (Choi, Oh, & Choy, 2009; Khan et al., 2012). Hence, many apparently contradicting results have been reported due to the use of different cell types and the test of a variable range of concentrations (Liu, Gao, Ai, & Chen, 2013).

The inhibitory concentration at 10% (i.e., 2 $\mu\text{g}/\text{cm}^2$) has been chosen to be further applied to study the other toxicological endpoints. This concentration is among the lowest used in the literature. It is always very important to reduce particle exposure as much as possible to keep a sufficient dose to study the underlying mechanisms of action while contributing to the effort to be as close as possible to human exposure levels (Leclercq et al., 2016). In exposed Balb/c mice by whole body inhalation to Fe_3O_4 NPs (i.e., 19.9 mg/m^3 over 4 hours), Teeguarden et al. (2014) reported target tissue doses in the bronchial (about 1 $\mu\text{g}/\text{cm}^2$) and the alveolar (0.003–0.13 $\mu\text{g}/\text{cm}^2$) regions. The Fe-NP dose of 2 $\mu\text{g}/\text{cm}^2$ we applied on to HBECs was also in the same order of magnitude as that deposited in the bronchial region of this in vivo model.

Over time, exposure to Fe-NPs only produced a relatively low levels of ROS without any significant oxidative damage, as carried out by glutathione status ([GSSG]/[GSH]) and MDA production. Feng et al. (2018), who exposed human ovarian cancer SKOV-3 cells and murine RAW 264.7 macrophages to relatively high concentrations of various Fe-containing NPs, noticed time-dependent intracellular ROS production. Liu et al. (2013) indicated that the most toxicities from Fe-containing NPs derived from ROS overproduction, which can thereafter damage cells by peroxidizing lipids, injuring DNA and proteins, modulating gene transcription, and altering the physiological function and regulated cell death. However, in this work, the relatively low ROS production induced by the low-dose Fe-NPs applied on to HBECs seemed not able to overwhelm the antioxidant defenses nor the repair capacities of HBECs (Garçon et al., 2000, 2001b, 2006). Bhattacharya et al. (2009) showed that a same dose of Fe-containing NPs (Fe_2O_3 , 50 nm), also roughly comparable with this used by Teeguarden et al. (2014), induced an almost similar decrease in cell viability but higher ROS production in human bronchial fibroblasts. Dwivedi et al. (2014) showed that a low dose of Fe-containing NPs (Fe_3O_4 , 174 nm agglomerate) induced a decrease of cell viability and oxidative damage, including lipid peroxidation and glutathione oxidation, in cancer-derived A549 cells. The apparent discrepancy between the data arising from the current literature and the original data from this work might rely on the use of different Fe-containing NPs, with their own physicochemical characteristics, and the use of different cell models, primary vs. transformed cells, from different target human

lung tissues. This closely reinforced the importance of using a relevant in vitro model, which could also help to reflect the normal human bronchial epithelium better.

To the best of our current knowledge, the studies dealing with the effect of Fe-containing NPs on DRG in the lungs are limited (Arenz, Hellweg, Stojicic, Baumstark-Khan, & Grotheer, 2006; Brandenberger et al., 2010; Foldbjerg et al., 2012; Monteiller et al., 2007; Park, Choi, Park, & Park, 2008). Hence, to go further ahead, DRG profiles of a set of selected target genes encoding proteins closely involved in oxidative stress, inflammation, DNA repair, apoptosis and other mechanisms such as mucus secretion were studied. Accordingly, oxidative stress, inflammation and cell cycle deregulation were among the main adverse cell outcomes reported as activated by a single short-term exposure of lung cells to Fe-containing NPs (Chen et al., 2016; Huang, Cambre, & Lee, 2017; Kornberg et al., 2017; Loxham et al., 2015; Stone et al., 2017). Indeed, IL-8 was first described as a chemoattractant cytokine, which plays an important physiological role in the biology of leukocytes and other cell types by controlling tissue homeostasis, cell recruitment and activation and guiding leukocyte movements under basal and inflammatory state mediators (Russo, Garcia, Teixeira, & Amaral, 2014). IL-13RA2 is a receptor for IL-13, which is a major inducer of fibrosis in many chronic infectious and autoimmune diseases (Fichtner-Feigl, Strober, Kawakami, Puri, & Kitani, 2006). Described primarily as a decoy, IL-13RA2 acts as a scavenger receptor, a potent antagonist of IL-13 activity in epithelial cells, and would be a potentially critical mediator of IL-13 clearance in humans (Kasaian et al., 2013). Granulocyte macrophage-colony stimulating factor (granulocyte macrophage-CSF), also known as CSF2, is an important survival, proliferation and differentiation factor of the progenitor cells for neutrophils and macrophages (Park et al., 2015). Shoeb et al. (2017), studying the toxicity of a complex welding-generated aerosol of incidental NPs and metals, such as Fe, in RAW264.7 cells, indicated elevated expression of prostaglandin-endoperoxide synthase 2 (PTGS2), also known as cyclooxygenase 2 (COX-2), thereby corroborating the development of a proinflammatory response. Cheng et al. (2012) showed dose- and time-dependent increases of PTGS2 in 1,2 naphthoquinone-exposed BEAS-2B cells whereas Ahn et al. (2008) demonstrated its significant increases, at both transcriptional and protein levels, in DEP-treated cells. In addition to proteolytic degradation of the lung parenchyma, matrix metalloproteinase (MMP)-associated activity also participates in a number of other processes, including the inflammatory response, mucus hypersecretion, vascular apoptosis/proliferation and profibrotic pathways (Navratilova, Kolek, & Petrek, 2016). During inflammation, proprotein MMP are activated through a cascade of proteolytic cleavage to yield active MMP that in turn activate cytokines (e.g., IL-8) and/or modify the binding interaction between some chemokines and their receptors (Foley et al., 2012, 2014). Lindner et al. (2012) noted alterations of MMP1 and MMP3 gene expression in lung cells under proinflammatory conditions. Even if there are only very few studies in lung cells about the possible role of *TNFSF11* gene, also called the receptor activator of nuclear factor- κB ligand (RANKL), an increasing body of evidence suggested that this receptor and its ligand play a

role in apoptosis (Rao, Cronin, Sigl, & Penninger, 2018; Sigl, Jones, & Penninger, 2016). A decrease of *TNFSF11* expression could also decrease the activation of anti-apoptotic protein, as a mechanism of defense towards HBEC exposure to Fe-NPs (De Castro et al., 2015). Taken together, the regulation of all these target genes in HBECs in response to their exposure to relatively low doses of Fe-NPs suggested a rapid activation of proinflammatory processes, without a clear ROS overproduction.

In this work, aiming to contribute to a better knowledge of the underlying mechanisms involved in the pathogenicity of lung disorders related to Fe-NPs, we developed a relevant primary culture model of HBECs to test the toxicity of well-characterized Fe-NPs generally typifying Fe-rich NPs emitted by metal industries. Applying this relatively low dose of Fe-NPs on to HBECs allowed us to obtain results that would be most representative for the deposited in vivo dose. HBECs were also able to produce relatively low levels of ROS, without evident oxidative damage, but to regulate quickly the transcription of some target genes closely involved in the proinflammatory response. Although this inflammatory process seemed to stay under control over time, in the case of this acute scenario of exposure, the future study of its evolution after a scenario of repeated exposure could be very interesting to evaluate the toxicity of Fe-NPs better.

ACKNOWLEDGEMENTS

This work was supported by the Université de Lille and the Conseil Régional du Nord-Pas de Calais (CPER-IRENI). The Agence de l'Environnement et de la Maîtrise de l'Energie (ADEME) is acknowledged for its financial support (PhD grant of Ludivine CANIVET). We would like to thank Anne Loyens from the "Plateforme de Microscopie Electronique. Imagerie Cellulaire, Tissulaire et Moléculaire" from the INSERM UMR837 JPARC (Lille) for her skilful assistance in cell observations by transmission electron microscopy.

CONFLICT OF INTEREST

The authors have no conflict of interest to report.
