Abstract— The paper describes how chipless RFID tags in motion can be read at higher distances than what is currently done without taking into account displacement. The movement results in the appearance of a tag backscattered field containing frequencies different from those emitted by the reader according to the Doppler effect. The use of these frequencies not generated by the reader considerably increases the reading distance of the tag, especially in a real environment. This paper is focused on a rotational movement of the tag. The proof of concept is carried out on elementary chipless tags which will be read up to 10 m.

Keywords— Chipless RFID, Micro-Doppler, Resonant Scatterer.

I. INTRODUCTION

Chipless RFID technology has been introduced as an effective solution for cost reduction in RFID market [1]. In this technology, silicon chips, as well as any electronic component, are excluded from the tag structure and so, the identification (ID) data is included in the geometric properties of the tags that are translated into its backscattering behavior [1], [2]. Among different types of frequency coded tags, Radio-frequency Encoding Particles (REP) is the most attractive approach as compact tags can be obtained with higher coding capacity [2]. Indeed, the REPs are composed of microwave resonators, and the ID can be associated to the resonance frequency, as well as to the amplitude, phase, and any polarimetric backscattering properties of each scatterer [2]. According to the best knowledge of the authors, any rigorous study has not been done to investigate the read range limitations of the chipless tags and to discuss about possible solutions for increasing the reading distance. Contrary to classical RFID UHF tags which modify their RCS, chipless tags cannot modulate their backscattered signal since the EM interaction with the chipless tag (and almost all materials in the background environment) can be modeled by linear time-invariant (LTI) systems. Thus, the backscattered signals from the tag and from the background share the same frequencies as the transmitted signal which significantly reduces the read range. Thus, the essential solution to enlarge the read range is to break the linearity or time-invariance of chipless tags.

In radar, the Doppler effect has been studied and used for many applications for decades [3]. The wave backscattered by a moving object will have different frequencies from those emitted by the transmitter. The study of periodic object movements (rotation or vibration in one or several directions) with small displacements with respect to the distance [4], is

Fig. 1. (a) Principle of the chipless sensor based on micro Doppler effect. (b) Simulated RCS of the dipole scatterer of different length l .

known as the micro-Doppler effect [5]. By considering the object exterior surfaces as perfectly conducting surface and large in size with respect to the wavelength, it is possible to establish analytical formulas describing how the backscattered power is distributed among harmonics around the frequency of the incident field [4], [5]. Recently the principle of micro-Doppler effect has been used to realize rotating beacons detectable with automotive FMCW radars [6].

The idea of the paper is to use the Doppler effect on basic chipless tags to allow detection over a reading distance higher than when the tag is stationary. To do this, the micro-Doppler equation is modified to take into account the resonant behaviour of the tags that allows their identification.

II. ANALYTICAL MODEL

A. Backscattering from rotating dipole as a chipless tag

Fig. 1(a) shows a dipole with a length l which is aligned along the y -axis and is rotating on a circle with a radius R . The rotation angular frequency of the dipole around its rotation axis (y -axis) is $\omega_r = 2\pi f_r$. The radiated far-field of a y -polarized antenna with gain G_A is incident on the dipole and the co-polarized scattered field is received by the same antenna. In addition, the induced current on the thin dipole can be perfectly modeled by a line current source with an omni-directional reradiation pattern as shown in

Fig. 1(a). Thus, the amplitude of the backscattered field does not change during the rotation of the dipole. The phase-varying backscattered fields from the rotating dipole can be accurately modeled using the classical rotation-induced micro-Doppler effect [5]. In the 2D representation of the problem, illustrated in the inset of Fig. 1(a), the dipole can be replaced by a rotating point scatterer in xz -plane. For a time-harmonic transmitted wave $s(t) = A \cos(2\pi f_0 t + \phi_0)$, with power $P_t = A^2/2$, the complex envelope of the periodic received signal can be obtained as [5]:

$$s_r^{ce}(t) = A e^{j\phi_0} \rho(f_0) e^{-2jk(R_0 + R \sin \omega_r t)} \quad (1)$$

where, $k = 2\pi f_0/c = 2\pi/\lambda$, c is the velocity of the light, and $\rho(f_0)$ is the frequency dependent reflectivity of the dipole resonator which is utilized here as a REP. Fig. 1(b) shows that the simulated RCS of the dipole depends on its length and so, this frequency dependency has been considered in (1). The periodic signal $s_r^{ce}(t)$ can be expressed by a Fourier series in time-domain as:

$$s_r^{ce}(t) = A_c \rho(f_0) \sum_{n=-\infty}^{+\infty} J_n(\beta) e^{-jn\omega_r t} \quad (2)$$

where $\beta = 4\pi R/\lambda$, $A_c = A e^{j\phi_0} e^{-j2kR_0}$, and $J_n(\beta)$ is the Bessel function of the first kind of order n . The Fourier transform of (2) gives (3), which clearly describes the newly generated frequency components of $n f_r$ due to the micro-Doppler effect, which is the vital point to increase the read range of the proposed rotating chipless tag.

$$S_r^{ce}(f) = A_c \rho(f_0) \sum_{n=-\infty}^{+\infty} J_n(\beta) \delta(f - n f_r) \quad (3)$$

B. Differential RCS for rotating chipless tag

Differential RCS has been introduced in [7] to determine the power of the modulated tag signal. Originally defined for UHF tags, this definition has however been extended to any modulating tag [8] and can be applied to the tags presented in this paper. The delta RCS can be computed directly from (3) while remarking that the power associated to the real signal is half of the one associated to the complex envelope:

$$\sigma_d(f_0) = \frac{(4\pi)^3 R_0^4}{2 P_t G_A^2 \lambda^2} \left(\int_{-\epsilon}^{\epsilon} |S_r^{ce}(f)|^2 df + \int_{+\epsilon}^{+\infty} |S_r^{ce}(f)|^2 df \right) \quad (4)$$

$$\sigma_d(f_0) = \sigma(f_0) [1 - J_0^2(\beta)] \quad (5)$$

where 2ϵ is the minimal bandwidth which allows to remove the power at $f = 0$, and $\sigma(f_0) = (|\rho(f_0)|^2 (4\pi)^3 R_0^4) / (G_A^2 \lambda^2)$ is the RCS of the short-circuited dipole at the frequency f_0 . Note that (5) has been obtained using the well-known equality $\sum_{n=-\infty}^{+\infty} J_n^2(\beta) = 1$. This relation allows to link the classical RCS to the delta RCS.

Fig. 2. Measurement bench used to characterize the micro-Doppler effect generated by the rotation of the tags. Dipole scatterers used in the study with length of 90, 73 and 58 mm and $D = 100 \mu\text{m}$ are shown in inset.

III. RESULT AND DISCUSSION

A. Measurement Bench

Measurement bench is presented in Fig. 2 and is composed of a VNA (HP 8720D) and a spectrum analyzer (Tektronix RSA3408A). Both instruments are respectively connected to the transmitting and receiving antennas (A.H. Systems, INC. SAS-571). Antennas have been placed in close proximity to tend to a monostatic configuration. Note that the VNA operates in CW mode and only acts as a RF source. Frequency can be set in-between 1 and 2.6 GHz and the output power has been set to 0 dBm. The spectrum analyzer acquires the backscattered signal over a span of 1 kHz around the CW generated by the VNA. Also, both instruments are synchronized using the same 10 MHz reference signal. Tags are placed on a rotating support of radius 3.7 cm and rotate at a speed of 70 turns/sec. The rotating support is placed at a distance of 1 m from the antennas to fulfill far-field condition.

Chipless tags considered in this paper are also presented in the inset of Fig. 2 and correspond to short-circuited dipole scatterers. Three tags have been designed using a $100 \mu\text{m}$ copper wire. To increase mechanical robustness, tags have been encapsulated in-between 2 layers of PET.

B. Backscattered Power Spectral Density

The backscattered PSD generated by the rotating tag is presented in Fig. 3. Since the environment is a LTI system, the received PSD (when the tag is not rotating) is only located at f_0 (or $f = 0$ after the demodulation done by the spectrum analyzer). When the tag is rotating, peaks located at $n f_r$ with an amplitude weighted by the Bessel function as predicted by (3) is observed, thus model and measurement are in a good agreement. Also, each tag can be differentiated using the amplitude of the backscattered sidelobes. For example, in Fig. 3 with $f_0 = 1.75$ GHz, Tag 2 has an amplitude which is higher than Tag 1 and 3. The same trend as seen in the RCS [see Fig. 1(b)] is observed at this frequency.

C. Identification

In Fig. 3, the PSD is clearly different from one tag to another. However, this way to identify each tag implies that all the tags have to be placed at the same distance from

Fig. 3. Measurement of the backscattered power spectral density for the 3 tags rotating at $f_r = 70$ Hz for a carrier frequency f_0 of 1.75 GHz. Empty corresponds to the PSD of the chamber when no object is rotating.

Fig. 4. Delta RCS as a function of the carrier frequency for the 3 rotating tags computed using measured backscattered PSD. Empty corresponds to the delta RCS of the chamber when no object is rotating.

the antennas. If distance is changed, the amplitude of the backscattered signal is also changed which makes the tag identification impossible. The variation of the delta RCS σ_d as a function of the frequency, given by (5), can be used as a metric which is independent of the measurement distance. Fig. 4 presents σ_d as a function of the carrier frequency; it presents a maximum at the resonant frequency of the dipole as it was predicted with (5) and Fig. 1(b). Also, the 3 resonant frequencies can clearly be separated which shows that the 3 tags can be identified only using the position of the peaks. Note that tags delta RCS have been obtained without using any empty measurement.

Finally, the dashed line presents the delta RCS when Tag 1 and 3 are placed (at the same time) on the rotating support. In this case, we can see that both resonators can be simultaneously identified. Thus, the design of a rotating chipless tag composed of several resonators can be realized [1], [2]. Coding capacity for this multi-resonator tag, assuming that the ID is coded with presence or absence of a given resonator can be estimated by dividing the total bandwidth (1.6 GHz) by the bandwidth of a single resonator (400 MHz). Thus, the proposed multi-resonator tag has a capacity of 4 bits in the

Fig. 5. Read range of the 3 different tags as a function of the equivalent distance considering a carrier frequency of 1.45, 1.75 and 2.18 GHz for Tag 1, 2 and 3 respectively. Noise floor of the system is observed at -90 dBm.

bandwidth 1 to 2.6 GHz.

D. Read Range

As presented in [1], classical chipless tags are usually characterized by a read range lower than 30 cm since both tag and environment are LTI systems. However, read range of the presented rotating tag can be determined using a modified radar equation obtained by replacing σ by σ_d [see (5)].

Modulated power P_{bsd} (i.e., power associated to the side lobes) has been measured as a function of the transmitted power P_t in the interval $[-50; +5]$ dBm at a fixed distance of 1 m in anechoic chamber. For each P_t value, the equivalent distance has been determined, assuming that a fixed value of $+5$ dBm has been used in by the VNA. Results are presented in Fig. 5 where we see that P_{bsd} is a decreasing function of the equivalent distance. Theoretical P_{bsd} considering the delta RCS estimated from Fig. 4 has also been added to the plot and presents a good agreement with the measured data. For high equivalent distances, measured power remains constant around -90 dBm due to the noise floor of the instrument. Read range of the rotating tags can thus be obtained by finding the distance at which the modulated power is higher than the noise floor. Results depends on the tag delta RCS and are equal to 15, 13 and 9.5 m for Tag 1, 2, and 3 respectively. These read ranges outperform the ones associated to classical chipless tag detection by a factor of 30.

IV. CONCLUSION

Identification of chipless tags exploiting the Doppler effect is introduced for the first time. A model taking into account the frequency behavior of the tag has been developed. The delta RCS of the tag has been obtained analytically and measured. The results are in accordance with the theory and show that reading distances higher than 10 m can be achieved. A rotational movement of the tag was studied for ease of implementation. However, the approach is not limited to this type of movement and this principle can be used on tags moving at a lower speed, in the case of translations for instance when the tagged objects are positioned on a conveyor belt.
