Abstract—This paper presents a fully adaptive Minimum Mean Square Error (MMSE) iterative equalization with a joint phase estimation, using various adaptive step-sizes scheme. To meet the requirement of fast convergence and low MSE over time-varying channels, we propose an original self-optimized algorithm whose step-sizes are updated adaptively and assisted by soft-information provided by the channel decoder in an iterative manner. Simulation results show that our proposal achieves better performance over various multipath time-varying channels, compared to the conventional equalizer using a fixed step-size.

Index Terms—turbo equalization, phase estimation, adaptive algorithms

I. INTRODUCTION

The choice of step-sizes for adaptive algorithms has a considerable impact, in particular on the UnderWater Acoustic (UWA) communication system performance; however, by essence, this choice is difficult in practice and often leads to severe performance degradation.

We consider this issue for two adaptive algorithms that are crucial at the receiving side when the channel is doubly selective: equalization and phase synchronisation. Indeed, iterative turbo equalization [1]–[3] can be difficult when the InterSymbol Interference (ISI) due to multipath propagation is severe; also, accurate adaptive phase recovery may be critical in the case of high Doppler frequency variations [4]–[10].

The performance of the standard Minimum Mean Square Error (MMSE) iterative equalization depends on its constant step-size [3], [11]–[14]; in particular, the step-size controls both the convergence speed and the steady-state MSE of the algorithm; hence it affects significantly the performance of the adaptive equalizer. Furthermore, for time-varying channels such as underwater acoustic channels, algorithms using constant step-sizes are unable to achieve a good trade-off between the performance and the convergence speed. However, most of the existing literature concerned with MMSE adaptive step-size filters [8], [9], [15]–[17] did not consider the case of turbo equalization; [18] (resp. [19]) proposed an iterative equalization scheme based on the least-symbol-error-rate [20] with a constant (resp. variable) step-size; besides it was not designed to track phase drifts of challenging channels, its high complexity makes it poorly suited for both embedded systems and fast time-varying channels.

In this paper, we propose an original adaptive step-size algorithm for joint equalization and phase estimation for

Fig. 1. System model.

which the soft information exchanged between the equalizer and the channel decoder can also be used for adjusting the adaptive step-size, as it is an appealing indicator of the symbol reliability. The proposed algorithm for joint phase recovering and equalization allows a faster convergence speed, a better tracking performance over time-varying channel and a lower mean square error compared to the constant step-size case.

The paper is organized as follows. Section II describes the system model. Section III presents the adaptive step-size equalization - phase estimation algorithm. Numerical results obtained over some time-varying channels and a real UWA channel are displayed in Section IV. At last, some conclusions are made in Section V.

II. SYSTEM MODEL

The transmission scheme is displayed in Fig. 1. A binary information sequence $\mathbf{b}$ is encoded by a channel encoder into a sequence of coded symbols $\mathbf{c}$ [21], [22]. A bit interleaver Π is then performed to increase the code diversity, and each set of $m = \log_2 M$ interleaved coded bits are mapped into a M-QAM complex symbol s_k in the alphabet χ . A known training sequence is added to the coded symbols, which allows the receiver to perform several baseband processing such as synchronization and frame detection [2], [23]–[27]. The obtained signal $\mathbf{s}$ is finally transmitted through a doubly-selective channel. In our simulations, we tested our proposal over an underwater channel provided by [28] (e.g. Fig. 2 shows some impulse responses of a BCH1 channel measured off the commercial harbour of Brest in France, over a distance of 800 m at different times) and also a synthetic channel provided by

Fig. 2. Impulse responses at time $t = 5, 10$ s of BCH1 channel.

[2]. The received symbols can be written as:

$$r_k = \sum_l h_l(k) s_{k-l} + w_k, \quad (1)$$

where at time index k , $h_l(k)$ indicates the channel response, and w_k is an Additive White Gaussian Noise (AWGN).

At the receiver side of Figure 1, both the phase variation and ISI caused by the time-varying multipath channel need to be combated to achieve good performance through several signal processing algorithms. Therefore, the receiver performs the equalization and phase synchronization algorithm as described in the next section. Thereafter, the obtained symbols z_k are fed into the Symbol to Bit Converter (SBC) in order to compute the Log-Likelihood Ratio (LLR) values from the equalized symbol z_k [2]:

$$z_k = \beta_0 \tilde{s}_k + \nu_k, \quad (2)$$

where $\beta_0 \tilde{s}_k$ is the desired signal with a constant bias factor β_0 and ν_k is a Gaussian noise of variance σ_v^2 . The LLRs of the mapped bits $l^i(s)$, ($i = 0, 1, \dots, \log_2 M - 1$) is given by:

$$LLR(l^i(s)) = \ln \frac{\sum_{x \in \mathcal{X}_b^1} \exp\left(-\frac{|z_k - \beta_0 x|^2}{\sigma_v^2}\right)}{\sum_{x \in \mathcal{X}_b^0} \exp\left(-\frac{|z_k - \beta_0 x|^2}{\sigma_v^2}\right)}, \quad (3)$$

where $l^i(s)$ is the i -th bit of symbol s and $\mathcal{X}_b^i$ denotes the set of the constellation points whose i -th bit is $b = 1$ or 0 .

Then, the channel decoder is applied; its extrinsic soft information output is used by the Bit to Symbol Converter (BSC) to obtain the soft estimated symbol $\tilde{s}_k$ [2]. Finally, the symbols $\tilde{s}_k$ are used in the next iteration of our proposed joint equalization - phase synchronization algorithm. Finally, after p_{max} iterations (i.e. equalization/channel decoder), a hard decision on the LLRs at the output of the decoder is made to estimate the user information bits.

III. THE PROPOSED ADAPTIVE TURBO EQUALIZER

A. Equalizer structure

Fig. 3 presents the equalizer - phase estimator structure; two filters $\mathbf{f}_k$ and $\mathbf{g}_k$ are fed by the output channel sequence $\mathbf{R}_k = [r_{k+L_1}, \dots, r_{k-L_1}]^T$ and the symbol sequence $\tilde{\mathbf{S}}_k = [\tilde{s}_{k+L_2}, \dots, \tilde{s}_{k-L_2}]^T$ respectively, where $\tilde{s}_k$ denotes either the

Fig. 3. Joint equalizer - phase estimator structure.

known preamble or the soft estimated symbol at the previous iteration for $p > 0$. The equalized symbol at time k is:

$$z_k = \mathbf{f}_k^T \mathbf{R}_k e^{-j\theta_k} - \mathbf{g}_k^T \tilde{\mathbf{S}}_k, \quad (4)$$

where $\mathbf{f}_k = [f_{-L_1}(k), \dots, f_{L_1}(k)]^T$ (resp. $\mathbf{g}_k = [g_{-L_2}(k), \dots, g_{L_2}(k)]^T$) is a transversal filter equalizer of length $2L_1 + 1$ (resp. $2L_2 + 1$), and θ_k is the estimated phase error; at each iteration p (less than p_{max}) the transversal filter $\mathbf{g}_k$ aims at filtering the residual ISI on the equalized symbol at the previous iteration. The index (p) is dropped in the sequel.

The coefficients of the filters are updated in order to minimize the MSE given by:

$$J(\mathbf{f}_k, \mathbf{g}_k, \theta_k) = \mathbb{E}_k \left(\mathbb{E}_x \left(\Pr(x | z_k) | x - z_k |^2 \right) \right), \quad (5)$$

where $\mathbb{E}(d)$ designates the expectation of d and:

$$\Pr(x | z_k) = \frac{\Pr(x) \Pr(z_k | x)}{\sum_{x' \in \mathcal{X}} \Pr(x') \Pr(z_k | x')}, \quad (6)$$

with:

$$\Pr(z_k | \tilde{x}) = \frac{1}{\pi \sigma_v^2} \exp\left(-\frac{|z_k - \beta_0 \tilde{x}|^2}{\sigma_v^2}\right). \quad (7)$$

It is important to note that in contrast to previous works [2], [8], [9], [11]–[13], the calculation of the MSE of equation (5) encompasses all synchronisation modes (Data-Aided (DA), Non-Data-Aided (NDA) and Code-Aided(CA)); in particular, for the CA mode, the probability of the constellation point $x \in \mathcal{X}$ can be computed using the LLR values (see (3)) at the output of the channel decoder.

With some basic mathematical derivations, we can obtain $\frac{\partial J}{\partial \mathbf{f}_k}$, $\frac{\partial J}{\partial \mathbf{g}_k}$ and $\frac{\partial J}{\partial \theta_k}$. Using the gradient descent algorithm, the filter coefficients $\mathbf{f}_k$, $\mathbf{g}_k$ and the estimated phase error θ_k are updated as:

$$\begin{cases} \mathbf{f}_{k+1} = \mathbf{f}_k - \frac{\mu}{2} \frac{\partial J}{\partial \mathbf{f}_k}, \\ \mathbf{g}_{k+1} = \mathbf{g}_k - \frac{\mu}{2} \frac{\partial J}{\partial \mathbf{g}_k}, \\ \theta_{k+1} = \theta_k - \frac{\gamma}{2} \frac{\partial J}{\partial \theta_k}, \end{cases} \quad (8)$$

where μ and γ are the step-sizes.

B. Adaptive step-size algorithm

We propose to optimize the step-sizes μ and γ in an adaptive manner on the coefficients trajectory so as to minimize the MSE (see (5)). Using the gradient descent algorithm, the step-sizes μ and γ are updated as:

$$\begin{cases} \mu_{k+1} = \mu_k - \frac{\alpha}{2} \frac{\partial J}{\partial \mu} \\ \gamma_{k+1} = \gamma_k - \frac{\beta}{2} \frac{\partial J}{\partial \gamma} \end{cases} \quad (9)$$

where $\frac{\partial J}{\partial \mu}$ and $\frac{\partial J}{\partial \gamma}$ can easily be obtained with some basic mathematical derivations.

It should be noted that, in contrast to state-of-the-art solutions [2], the proposed adaptive step-sizes are continuously and blindly updated on the whole information burst and exploit the soft information of each received symbol provided by the channel decoder at the previous iteration; this contributes to a good equalization - phase error estimation performance. In addition, note that for the adaptive step-size equalizer, the values of the second-order step-sizes α and β do not influence considerably the system performance, and can therefore be chosen in a large range.

IV. SIMULATION RESULTS

A. Synthetic time varying channel

In our simulations, a training sequence of 100 symbols is transmitted before each user frame. At the receiver side, p_{max} is fixed to 10. We consider the synthetic channel [2]:

$$h_l(k) = \sqrt{\frac{P_l}{I}} \sum_{i=1}^I e^{j(k\epsilon\pi \cos \psi_{l,i} + \zeta_{l,i})}, \quad (10)$$

where the Doppler shift is characterised by ϵ , P_l denotes the mean power of the l -th channel path, $\psi_{l,i}$ and $\zeta_{l,i}$ are uniform random variables over $[0, 2\pi[$; I is fixed to 10 and (10) has three paths having all the same mean power [2] in our simulation.

We evaluate the performance of our proposal by considering 2 scenarios, for all of which the initial Doppler shift is equal to 0.001 and linearly changes to reach the value ϵ_{max} at the end of the received block. In the first scenario, we consider a relatively slow variation where $\epsilon_{max}^1 = 0.002$, for the second scenario, the Doppler shift at the end of the received block is equal to $\epsilon_{max}^2 = 0.005$. The number of taps for $\mathbf{f}_k$ and $\mathbf{g}_k$ are equal to 13 and 19 respectively, the central coefficient of $\mathbf{f}_k$ is set to 1.

Fig. 4 (resp. Fig. 5) compares the BER performance between the proposed fully adaptive step-size algorithm over the whole frame, the so-called "CS tracking" algorithm for which the step size is adaptive during the initial training sequence and then fixed during the information frame to the value reached at the end of the preamble, and finally the algorithm for which the step size is fixed to the initial value for all symbols transmitted over the time varying channel (10) with ϵ_{max}^1 (resp. ϵ_{max}^2) for both the QPSK and 16-QAM constellations. It can first be observed that for all scenarios, the proposed fully adaptive step-size algorithm achieves a considerable performance gain

Fig. 4. BER comparison over the channel (10) for $\epsilon_{max}^1 = 0.002$ for both the QPSK and the 16-QAM constellations.

Fig. 5. BER comparison over the channel (10) for $\epsilon_{max}^2 = 0.005$ for both the QPSK and the 16-QAM constellations.

compared to the conventional constant step-size algorithm. Moreover, it can be observed that the gain obtained with the proposed algorithm compared to the conventional algorithm increases with the Doppler shift variation speed.

Fig. 6 displays the MSE curves for $\epsilon_{max}^2 = 0.005$ for QPSK constellation at 8.5 dB for all studied algorithms. It can be observed that the proposed fully adaptive step-size algorithm has the best tracking performance among the considered algorithms.

B. Watermark [28]

User frames of 1024 bits are coded with a turbo code of rate 1/3 with generator polynomials equal to $(5, 7)_{octal}$; the coded bits are then interleaved and transformed into a sequence of M-QAM symbols. A training sequence of 511 symbols is transmitted before each user frame and p_{max} is fixed to 5. The information is transmitted at a bit rate of 1.4 kbit/s at a 35 kHz carrier frequency over the BCH1 channel [28] (e.g.

Fig. 6. MSE comparison for $\epsilon_{max}^2 = 0.005$ for the QPSK constellation

Fig. 7. BER comparison over the channel BCH1 [28].

Fig. 2). The number of taps for f_k and g_k are 21 and 31 respectively.

Fig. 7 compares the BER performance between the proposed fully adaptive step-size algorithm, the so-called “CS tracking” algorithm for which the step-size is adaptively updated over the preamble, followed by a tracking period with a constant step-size obtained at the end of the preamble, and finally the algorithm for which the step size is fixed to the initial value for all symbols transmitted over the underwater channel BCH1 for the QPSK constellation. It can be observed that the proposed fully adaptive step-size algorithm achieves a gain of 1.5 to 2 dB compared to the conventional constant step-size algorithm.

V. CONCLUSION

This paper proposes an original new joint equalizer - phase estimator algorithm with adaptive step-sizes. It leads to good BER performance by achieving a good trade-off between the convergence speed and accuracy over time-varying channels. Simulation results of our proposal shows a significant BER

improvement compared to the conventional solutions, in particular for time-varying channel with high Doppler shifts. Finally, in the future it seems very interesting to design fully adaptive algorithms for equalization and phase synchronisation for rotated constellations [29]–[34] so as to take advantage of the inherent diversity of rotated constellations without any bandwidth loss.
