Abstract:

Carbon dioxide (CO₂) storage in geologic formations is an attractive means of reducing greenhouse gas emissions. The main processes controlling the migration of CO₂ in geological formations are related to convective mixing and geochemical reactions. The effects of heterogeneity on these coupled processes have been widely discussed in the literature. Recently, special attention has been devoted to fractured geological formations that can be found in several storage reservoirs. However, existing studies on the effect of fractures on the fate of CO₂ neglect the key processes of geochemical reactions. This work aims at addressing this gap. Based on numerical simulations of a hypothetical reservoir, we explore the effect of fracture properties and topology on the domain's storage capacity at different rates of CO₂ mineral dissolution. It is found that, the fractures not only can help the mixing convection and reaction process in the domain but also may play a restrictive role in entering dissolved CO₂ and hinder the plume fingers from growing. The hypothetical case is relevant in providing preliminary understanding but can show varying degrees of geological realism. For more representative geology, we investigate the migration-dissolution of buoyant CO₂ on a large-scale outcrop of a volcanic basalt rock formation. The results show that neglecting thin fractures can significantly affect the predicted amount of trapped CO₂. The storage capacity is more sensitive to heterogeneity at low dissolution rates. The findings are useful for the management of CO₂ sequestration in fractured domains.

1. Introduction

Energy transition, sustainable development, and climate change are currently the main significant challenges facing humanity. Since the mid-20th century, due to anthropogenic greenhouse gas emissions and activities, global warming has been raised, and the increase in global temperature is estimated at 0.2°C above pre-industrial levels (Masson-Delmotte et al., 2018). This caused various observed changes in the climate system, such as the melting of the ice caps, sea-level rise, intensified heatwaves, and longer drought periods in most semiarid regions (NASA, 2018). The Intergovernmental Panel on Climate Change (IPCC) predicts a temperature rise of 1 to 6°C by the end of the century, and the impact of climate change on humanity varies with the ability of social systems to adapt or mitigate changes (Masson-Delmotte et al., 2018).

It is assessed that the major reason for the increase in the global temperature of the Earth's surface is the multiple anthropogenic sources that cause the accumulation of greenhouse gas in the atmosphere (Rose et al., 2017). Carbon dioxide (CO₂) is the primary greenhouse gas; therefore, considerable mitigation of CO₂ emissions is the most effective way to reduce global warming (NASA, 2018). This calls for new sources of low-carbon energy. But in a transition period, there is a need for efficient techniques to reduce CO₂ emission to the atmosphere. Among several available techniques, the storage of CO₂ in geological formations is one of the leading technological ways to dramatically reduce anthropogenic emissions of greenhouse gas (Bachu et al., 2007; Gough, 2016; Michael et al., 2010; Orr, 2009). Injecting CO₂ into oil- and brine-bearing reservoirs is a technology to store captured anthropogenic CO₂ beneath the Earth's surface. The sequestration of CO₂ process for mitigating greenhouse gas involves the capture and transportation of CO₂ from anthropogenic sources and then injecting of supercritical CO₂ into underground geologic formations (Boot-Handford et al., 2014). The Paris Agreement on climate change estimated

that this technique would have a pivotal role in reducing greenhouse gas emissions (Rogelj et al., 2016).

CO₂ geological sequestration is a complex technology that involves a consecutive series of capture, transport, and sequestration/trapping processes. It requires knowledge and skills from geology, fluid mechanics, chemistry, geochemistry, hydrogeology, and environmental science. Current research questions in CO₂ geological sequestration focus on the improvement of the injection techniques (Hoteit et al., 2019; Sigfusson et al., 2015), ensuring safe and successful implementation (Romasheva and Ilinova, 2019; Singh and Islam, 2018; Soltanian et al., 2019), enhancement of reservoirs capacity (Kim et al., 2017; Raziperchikola et al., 2013), and assessment and prediction of the geological and environmental impacts (Chen et al., 2018). A key point in addressing these research questions relies on a good understanding of the fate of CO₂ in geological formations. The most important processes controlling the injected CO₂ are density-driven convection (DDC) and precipitation/dissolution (Kim et al., 2019; Mojtaba et al., 2014). In fact, after injecting supercritical CO₂ into a reservoir, because of the buoyancy effects (density and viscosity of CO₂ are 70% and 10% those of water), CO₂ migrates upward to spread over the caprock at the reservoir top surface, and then, it dissolves into the ambient native groundwater (Kim et al., 2019; Mojtaba et al., 2014). This forms the carbonic acid that has a higher density than water. Mixing processes between carbonic acid and lower groundwater take place by molecular diffusion. The density difference between carbonic acid and water induces gravitational instability. Thus, unstable DDC processes occur, and the fingering phenomenon appears. Fingering processes cause an enhancement of the mixing between carbonic acid and water. In the under-layers, the acidified water, in the long term, initiates mineral precipitation/dissolution reactions with the ambient geological formations (Soltanian et al., 2019).

The processes of DDC dissolution and mineral precipitation are fully coupled. Interactions between these processes during CO₂ sequestration have been the subject of several theoretical, numerical, and experimental studies. A widely discussed issue is the CO₂ dissolution in resident brine (i.e., solubility trapping) during sequestration in saline aquifers (Emami-Meybodi et al., 2015; Jafari Raad et al., 2019; Mojtaba et al., 2014; Tang et al., 2019). A comprehensive review of modeling and experimental works related to convective dissolution of CO₂ in saline aquifers is presented in (Emami-Meybodi et al., 2015). In the underground geologic formations, the dissolution of CO₂ in water increases acidity. Thus, under low-pH conditions, several primary minerals of the host rocks dissolve into the formation water. This increases the concentration in cations such as Ca²⁺, Mg²⁺ and Fe²⁺. By reactions with the existing cations carbonic acid can form carbonate minerals such as CaCO₃, MgCO₃, and FeCO₃. This phenomenon is called mineral trapping (Zhang et al., 2011; Soltanian et al., 2019). The reaction rates of the geochemical reactions depend on several in situ conditions such as pressure and temperature (Bachu et al., 2015). Processes of mineral trapping are slower than solubility trapping and occur over a longer (hundreds of years) geologic timescale (Bachu et al., 2015; Aminu et al., 2017). Such reactions enhance the spread of the dissolved CO₂ and increase the safety of geological storage. Thus, it is important to understand the impact of geochemical reaction between carbonic acid and the host rocks' to evaluate the ability of a reservoir in storing CO₂ in the long-term stability (Islam et al., 2016a; Rochelle et al., 1999). This topic has been discussed in the literature (Ennis-King and Paterson, 2007; Ghesmat et al., 2011; Ward et al., 2015). Recently, Babaei and Islam (2018) investigated the effect of convective-reactive CO₂ dissolution taking into account the mass transfer with immobile water. Erfani et al. (2020) studied the signature of geochemistry on DDC of CO₂ in sandstone rocks. They showed that geochemical reactions play a major role in the convective-diffusive flow of CO₂. Strong interaction between geochemical and DDC

processes has been observed. [Fu et al. \(2015\)](#) demonstrated that the dissolution of carbonate rock initiates in regions of locally high mixing, but the geochemical reaction stops significantly earlier than the shutdown of convective mixing. [Ghoshal et al. \(2017\)](#) showed that the high dissolution rates intensify the fingering phenomenon. A significant issue here is the impact of the geochemical reactions on the hydraulic properties of the reservoir such as porosity and conductivity ([Hidalgo et al., 2015](#)). The importance of this process depends on the geological characteristics of rocks.

The coupled processes of DDC and mineral dissolution/precipitation can be affected by ambient rocks. Heterogeneity has been found to play a major role in controlling the DDC-dissolution processes of CO₂. Heterogeneity impacts on convection-dissolution processes of CO₂ have been the subject of several studies. For instance, Kong and Saar ([Kong and Saar, 2013](#)) investigated the effect of stochastic heterogeneity on DDC processes during the dissolution of CO₂ in brine. Based on numerical experiments, [Islam et al. \(2016b\)](#) showed that DDC and dissolution processes are influenced primarily by the heterogeneity in grain size. [Dai et al. \(2018\)](#) investigated the effectiveness of the heterogeneity-induced trapping mechanism. Based on a site application, they showed that heterogeneity-assisted trapping has a greater areal extent for secure offshore CO₂ storage than gravitational trapping. Fractured domains are a particular type of heterogeneity. Fractures can generate preferential flow pathways and may increase the possibility of CO₂ leakage from the geological formation, which can cause significant ecological risks ([Zhang et al., 2018](#)). Several ecological consequences of CO₂ leakage on marine ecosystems are discussed in [Molari et al. \(2018\)](#) and [Borrero-Santiago et al. \(2020\)](#). [Fischer et al. \(2016\)](#) investigated the effect of CO₂ storage on groundwater. For instance, pressure increase below the caprock, due to CO₂ injection, can generate a preferential flow through faults and fractures that may exist in the caprock formation ([Fitts and Peters, 2013](#)). Preferential flow through Fractures and faults can make

increase the risk of leakage through abandoned wells (Huo and Gong, 2010). The ongoing project DETECT (<https://geoenergy.hw.ac.uk/research/detect/>) aims at evaluating the risk of CO₂ leakage along fractures of the primary caprock. Thus, in principle, densely fractured geological formations are usually unsuitable for safe CO₂ sequestration (Kim et al., 2019). However, fractures and faults can be observed in several storage reservoirs such as in Algeria, the Appalachian Basin and Montana in the USA, and Janggi site in South Korea (Kim et al., 2019; Raziperchikolaee et al., 2019,2020). In certain sites, fractures are stimulated, by hydraulic fracturing, in order to improve the storage capacity of saline aquifers (Iding and Ringrose, 2010; Middleton et al., 2014; Raziperchikolaee et al., 2013).

The effects of fractures on non-reactive DDC processes have been extensively investigated in the literature but not in the context of CO₂ sequestration (Hirthe and Graf, 2015; Jafari Raad and Hassanzadeh, 2018; Shafabakhsh et al., 2019; Simmons et al., 2008). Recently, Kim et al. (2019) investigated the effect of fractures on convective mixing during CO₂ sequestration, but they neglect reactive processes. However, several studies showed that fractures can affect the reaction processes (Chaudhuri et al., 2008; Liu et al., 2017). Thus, it is important to understand the role of fractures on coupled CO₂ convective mixing and geochemical processes in order to evaluate and predict CO₂ trapping mechanisms in fractured geological formations. To the best of our knowledge, this topic has not been investigated in the past. Thus, this work aims at developing a comprehensive study on the effects of various fracture configurations on coupled mineral dissolution and DDC processes. Our methodology is based on numerical modeling which is considered as the most suitable tool to understand CO₂ trapping mechanism, from the economical and practical point of view (Li and Jiang, 2017; Jafari Raad and Hassanzadeh, 2017; Soltanian et al., 2019). Conclusions learned from numerical models are helpful in enhancing our understanding of physical processes and in addressing current research questions related to CO₂ geological sequestration. Thus, based

on COMSOL Multiphysics, we develop a model that couple Darcy's law with mass transport equation under variable density, which is a function of dissolved CO₂ concentration. The fractures are considered explicitly via the discrete fracture model available in COMSOL. We consider simplified kinetic dissolution reaction of carbonic acid and calcium carbonate as in [Kim et al. \(2019\)](#) and the references therein. The model is first applied on a hypothetical domain overlaid by the supercritical layer of CO₂, under different configurations of fractures ([Babaei and Islam, 2018](#); [Kim et al., 2019](#)). We evaluate the effect of fracture characteristics, topology, and density on the total CO₂ flux entering the domain, which is used as a metric of the domain storage capacity. The problem of a synthetic reservoir with hypothetical fractured configurations is relevant in providing preliminary insight on the effect of fractures on CO₂ convection-dissolution processes but can show varying degrees of geological realism. For more representative geology, we apply the numerical model on a large-scale outcrop of a volcanic basalt rock formation in Lebanon. Based on the outcrop analogy we evaluate the capacity of fractured volcanic basalt rocks in trapping CO₂.

2. Governing equations and conceptual and numerical models

2.1. Mathematical model

After the injection of CO₂ into an aquifer, the CO₂-rich fluid at the caprock has a higher density than the native formation fluid; therefore, the CO₂-rich water will promote carbonate dissolution in the domain. The experiments on carbonate rock samples ([Elkhoury et al., 2013](#)) have indicated that the interaction between the CO₂ solution and rocks results in the formation of carbonate minerals through a series of geochemical reactions. These mechanisms depend on the pressure, temperature, acidity, chemical composition of the brine, and the mineralogy of the rocks ([Matter et al. 2007](#)). The precipitation of Ankerite depends on the rate of

reduction of mineral precursors such as goethite (Xu et al. 2004). In this work, we only focus on calcium carbonate dissolution.

The chemical system of the aqueous phase reactions and mineral-fluid reactions are summarized by the following chemical reactions. These reactions include acidification and carbonation of the native formation and potential mineral dissolution (Ghoshal et al., 2017; Izgec et al., 2005; Marini, 2006).

The reactions above can be combined into the following main geochemical reaction:

Among the reactive species in the chemical system, $\text{CO}_{2(\text{aq})}$ and calcium carbonate ($\text{CaCO}_{3(\text{s})}$) are selected as primary species (Babaei and Islam, 2018).

Reactive natural convection of dissolved CO_2 into the water in the porous matrix is governed by variable-density flow and mass transport equations. The mass conservation is ensured by the continuity equation and the velocity based on Darcy's law as follows:

$$\varepsilon_m \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0 \quad (3)$$

$$\mathbf{u} = -\frac{k_m}{\mu} (\nabla p - \rho \mathbf{g}) \quad (4)$$

Where ε_m is the porosity of the medium [-], ρ is the mixed fluid density [ML^{-3}], t is the time [T], $\mathbf{u}$ is the velocity [LT^{-1}], k_m is the intrinsic permeability of the porous matrix [L^2],

μ is the fluid dynamic viscosity [$\text{ML}^{-1}\text{T}^{-1}$], p is the pressure [$\text{ML}^{-1}\text{T}^{-2}$], and g is the gravity [LT^{-2}].

The convection-diffusion equation coupled to geochemical reactions for each chemical species in a non-deformable porous medium is as the following mass balance equations:

$$\varepsilon_m \frac{\partial c_{CO_2}}{\partial t} + \nabla \cdot (\mathbf{u} c_{CO_2} - \varepsilon_m D_m \nabla c_{CO_2}) = r_{chem,CO_2} \quad (5a)$$

$$\varepsilon_m \frac{\partial c_{CaCO_3}}{\partial t} = r_{chem,CaCO_3} \quad (5b)$$

Where c_{CO_2} and c_{CaCO_3} are the solute concentration [ML^{-3}], and r_{chem,CO_2} and $r_{chem,CaCO_3}$ are the reaction terms [$\text{ML}^{-3}\text{T}^{-1}$] for CO_2 and CaCO_3 , respectively. For these two species, the reaction terms which are assumed to be second-order can be written as (Babaei and Islam, 2018; Ghesmat et al., 2011):

$$r_{chem,CO_2} = -k_r a_v c_{CO_2} (c_{CaCO_3})^n \quad (6a)$$

$$r_{chem,CaCO_3} = -\varepsilon_m k_r a_v c_{CO_2} (c_{CaCO_3})^n \quad (6b)$$

Where k_r is the reaction rate constant [$\text{L}^4\text{M}^{-1}\text{T}^{-1}$], a_v is the mineral surface area available for reaction per volume of the medium [L^{-1}], and n is the rate of the reaction which is equal to 1 for the second-order reaction (Brezonik, 2018).

Finally, Equations (3), (4) and (5) are coupled with Boussinesq approximation by a linear function which relates the density (ρ) and the concentration of CO_2 (c_{CO_2}) as follows:

$$\rho = \rho_0 [1 + \beta (c_{CO_2} - c_{initial\ CO_2})] \quad (7a)$$

$$\beta = \frac{1}{\rho_0} \left(\frac{\partial \rho}{\partial c_{CO_2}} \right) \quad (7b)$$

Where ρ_0 is the density of fresh-water [ML^{-3}], β is the volumetric expansion coefficient in respect to the concentration of dissolved CO_2 . We assumed the effect of CO_2 on the density of water is linear and $\beta > 0$.

To generalize the results and characterize the mixing convection, allowing its comparison and application to different scales and conditions, we use the following dimensionless quantities to obtain the dimensionless form of governing equations.

$$\begin{aligned} x^* &= \frac{x}{H}, \quad y^* = \frac{y}{H}, \quad t^* = \frac{D_m t}{H^2} \\ u^* &= (u_x^*, u_y^*) = \left(\frac{Hu_x}{\varepsilon_m D_m}, \frac{Hu_y}{\varepsilon_m D_m} \right), \quad P^* = \frac{k_m}{\varepsilon_m D_m \mu} P \\ c_{CO_2}^* &= \frac{c_{CO_2} - c_{initial\ CO_2}}{c_{Max\ CO_2} - c_{initial\ CO_2}}, \quad c_{CaCO_3}^* = \frac{c_{CaCO_3}}{c_{initial\ CaCO_3}} \end{aligned} \quad (8)$$

Applying the above change of variables gives the following dimensionless governing equations. Eq. (11) represent the mass conservation and Eq. (12) is for the convection-diffusion equation coupled with reaction.

$$u^* = -\nabla^* P^* - Ra \cdot c^* \quad (9)$$

$$\frac{\partial c_{CO_2}^*}{\partial t^*} + \nabla^* \cdot (u^* c^* - \nabla^* c^*) + Da \cdot c_{CO_2}^* \cdot c_{CaCO_3}^* = 0 \quad (10a)$$

$$\frac{\partial c_{CaCO_3}^*}{\partial t^*} + Da \cdot \varepsilon_m \cdot c_{CO_2}^* \cdot c_{CaCO_3}^* = 0 \quad (10b)$$

Where Ra and Da are dimensionless numbers known as Rayleigh number and Damköhler number, respectively.

The non-dimensional Raleigh number (Ra) relates the ratio of the buoyancy forces that drive flow to diffusive forces that dissipate it. This parameter governs the natural convection processes, and it is used to characterize the onset of free convection. Ra is defined by (Prasad and Simmons, 2003):

$$Ra = \frac{k_m(\rho_s - \rho_0)gH}{\mu\epsilon D} \quad (11)$$

In this work, Ra is defined using the permeability of the porous matrix (k_m).

The dimensionless Damköhler number (Da) expresses the strength of geochemical reactions in porous media, and it is defined as the ratio between reaction and diffusion rates. We use this parameter to characterize the reactivity in the model. A high Da indicates a system with high reactivity due to the occurrence of fast reactions. In contrast, a low Da means the chemical reaction is sufficiently slow as if no reactions were present; therefore, convective mixing could not occur (Babaei and Islam, 2018; Fu et al., 2015; Sainz-Garcia et al., 2017). Using the definition presented by (Ghesmat et al., 2011) for the second-order reaction over convection, Da can be written as follows:

$$Da = \frac{k_r a_v H^2}{\epsilon D \Delta c} \quad (12)$$

2.2. Conceptual and numerical models

The domain and boundary conditions of a two-dimensional 1 (m) × 1 (m) hypothetical reservoir are similar to the work of (Kim et al., 2019) and are shown in Fig. 1. In this reservoir, there is an initial concentration of Calcium Carbonate (CaCO_3) dissolution as an initial condition. At the top surface, there is a dissolved CO_2 layer overlaying the domain with sinusoidal perturbation to initiate downward propagation of the dissolved CO_2 fingers and to trigger instability. This perturbation is equal to $C_{\text{CO}_2} = I + A \cdot \sin(2\pi x/\lambda)$, where A is amplitude and λ is the wavelength of the sinusoidal perturbation with the values of 0.01 and 1/12 respectively similar to (Kim et al., 2019). The lateral boundaries are considered to have periodic boundary conditions regarding the limitation of using a small domain size (Martinez and Hesse, 2016). The bottom boundary is assumed to be impermeable. The physical parameters used in this work are summarized in Table 1.

Fig.2. (a) Model domain with initial and boundary conditions. (b) The chemical system of the injected CO₂ in the domain.

Table 1. Physical parameters used in COMSOL.

Parameter	Variable	Value
Length	L	1 (m)
Height	H	1 (m)
Density of fresh-water	ρ_0	1000 (kg/m ³)
Density of CO ₂ -water at the top boundary	ρ_s	1010 (kg/m ³)
Concentration at the top boundary	c_b	$1 + A \cdot \sin(2\pi x / \lambda)$
Amplitude of sinusoidal perturbation	A	0.01
Wavelength of sinusoidal perturbation	λ	1/12 (m)
Porosity of the medium	ε_m	0.3
Diffusion coefficient	D_m	1×10^{-9} (m ² /s)
Dynamic viscosity	μ	5×10^{-4} (kg/(m·s))
Gravitational acceleration	g	9.8 (m/s ²)
Pressure at the top boundary	P_b	10 (MPa)
Intrinsic permeability of the medium ¹	k_m	$3.8 \times 10^{-13} : 6.1 \times 10^{-12}$ (m ²)
Intrinsic permeability of fracture ¹	k_f	$k_m / 1000$
Rate of reaction ²	$k_r a_v$	$0 : 3 \times 10^{-7}$ (m ³ /(s·mol))
Fracture length	L_f	0.8 (m)
Porosity of fracture	ε_f	0.5
Fracture aperture	$2b$	0.002 (m)

¹ Range of variation based on Ra ² Range of variation based on Da

In this study, we investigated scenarios including single fractures with different positions and angles, and also networks of orthogonal fractures. By varying the Rayleigh number and Damköhler number, there are 72 fracture cases (18 cases for each scenario), as summarized in Table 2.

Table 2. Simulation cases of fractured scenarios.

Scenarios	Cases			Varying parameters
Horizontal fracture (HF)
	HF1 ($y = 0.75H$)	HF2 ($y = 0.5H$)	HF3 ($y = 0.25H$)	
Vertical fracture (VF)				$Ra = 1000, 4000$
	VF1 ($x = 0.25L$)	VF2 ($x = 0.5L$)	VF3 ($x = 0.75L$)	$Da = 0, 100, 1000$
Inclined fracture (IF)
	IF20 ($\theta = 20^\circ$)	IF45 ($\theta = 45^\circ$)	IF70 ($\theta = 70^\circ$)	
Network of orthogonal fractures (NF)
	NF1	NF2	NF3	

COMSOL Multiphysics (COMSOL, Inc., Palo Alto, CA, USA), which is a commercial finite element simulation package, was used in this work to perform the numerical simulations. To simulate the convective-reactive transport, we coupled the “Darcy’s flow” interface from the “Subsurface flow” module and the “transport of diluted species in porous media” interface from the “chemical species transport” model. Since there are two primary chemical components (CO_2 and CaCO_3) reacting in the model, we added separate “transport of diluted species in porous media” interface for each species. For CaCO_3 , we drop the convection and diffusion operators. The kinetic dissolution reactions are included as source terms in the transport equations. To include fractures via the discrete fracture approach (1D), we used the interface “Fracture flow” as in (Koohbor et al., 2019; Mozafari et al., 2018; Shafabakhsh et

al., 2019). The system of flow and transport equations are solved simultaneously using the fully coupled approach in COMSOL. This leads to more expensive simulations in terms of CPU time but allows for avoiding numerical errors related to the operator splitting approach.

3. Results and Discussion

We considered the fractured scenarios described in Table 2. We examined reactive and non-reactive cases for each scenario and compared them with the homogeneous case (base case) in different combinations of convective flow (as different Ra) and rate of chemical dissolution (as different Da). As presented in Table 2, in this study, $Ra = 1000$ and 4000 are referred to as medium and high convective flow; and $Da = 0, 100$, and 1000 are referred to as non-reactive, slow-reactive, and fast-reactive respectively.

Total mass flux of CO_2 at the top boundary entering in the domain (TF_{top}) is a measurable characteristic that is used in this study to quantify the simulation results. The non-dimensional form of this parameter is defined as:

$$TF_{top}^* = \frac{TF_{top} \times H}{\epsilon_m D_m \Delta c} \quad (13)$$

Which is known as Nusselt number (Ataie-Ashtiani et al., 2014) and defined as the ratio of the total mass flux through a upper layer and diffusive flux. It can be divided into two terms:

The convective total flux, which is due to the advection process ($TF_{adv,top}^*$) and the total diffusive flux ($TF_{diff,top}^*$). In addition, total mass flux of CO_2 passing through the fracture (TF_f) is another measurable characteristic in this work. The non-dimensional total flux through the fracture (TF_f^*) has the same form as TF_{top}^* , and can be divided in convective ($TF_{adv,f}^*$) and diffusive ($TF_{diff,f}^*$) total flux.

In what follows, we investigated each fractured scenario, and finally, we conduct a field-scale exploration of density-driven convection in a deep geological formation.

3.1. Horizontal Fracture (HF)

In this section, we examine horizontal fractured (HF) scenario and compare them with the homogeneous case (base case) in different values of Ra and Da . This scenario has three cases of different positions of horizontal fractures, as presented in Table 2. Fig. 2 represents this comparison by showing the dimensionless total flux of CO_2 entering the domain from the top boundary (TF^*_{top}) during a period of time, which is set to $t^* = 0.015$ (the equivalent of 0.5 year) in this work. As expected in the bar charts, the values of TF^*_{top} for reactive cases ($Da = 100$ and 1000) are more than the non-reactive cases ($Da = 0$). The reason is that in reactive cases, there is dissolution of CO_2 in reaction with $CaCO_3$, and as a result of this dissolution, an increase in the gradient of CO_2 concentration would appear at the top boundary, which causes an increase in the rate of entering total flux of CO_2 .

Considering $Ra = 1000$ (which represents having medium convective flow in this study) in Fig. 2(a), as one can observe, TF^*_{top} of HF1 is lower than the base case for both non-reactive case ($Da = 0$) and slow-reactive case ($Da = 100$). This is because horizontal fractures in the domain play a restrictive role in entering of dissolved CO_2 . Also, we can see this concept in Fig. 2(a) in comparison of base case with HF2 and HF3 for these two amounts of Da , but in a lower difference because of the fact that the fracture in the cases of HF2 and HF3 are at middle and bottom of the domain respectively, and they have a lesser influence on the entering flux. As depicted in Fig. 3, which shows the concentration distribution of dissolved CO_2 at $t^* = 0.01$ for different cases, for $Da = 0$ and 100 , it can be clearly seen that the fractures inhibit the growth of fingers. Therefore, there would be a lower amount of CO_2 dissolution, and as a result, a lesser amount of flux enters the domain. Fig. 4 presents the variation of both convective and diffusive total fluxes at the top boundary versus t^* for $Ra = 1000$ and $Da = 0$ and 100 for the base case and HF1. First of all, by comparing the non-reactive ($Da = 0$) base case with HF1, for both convective and diffusive fluxes, it is shown that the base case has a

higher amount of $TF_{adv,top}^*$ and $TF_{diff,top}^*$ during the period of time ($t^* = 0.015$), and this confirms the restrictive role of fractures. However, in comparison of the reactive ($Da = 100$) base case with HF1, we see an opposite trend for diffusive flux after the first stage of mixing ($t^* = 0.0045$), but for convective flux, we do not see any specific trend. (As shown in Fig. 3) Diffusion is dominant around edges and tips of the fingers, and existence of fracture helps the diffusion mechanism as it spreads dissolved CO_2 ; therefore, in Fig. 4(b) $TF_{diff,top}^*$ for reactive HF1 is higher than reactive base case, and since the more CO_2 dissolved in water, the more diffusive flux of CO_2 enters from the top boundary readily. Nonetheless, comparison of reactive base case with HF1 in Fig. 4(a) reveals that while the fracture helps the mixing by convection and reaction processes, it inhibits the entrance flux of CO_2 , and it is why the trend of $TF_{adv,top}^*$ curves for these two cases are not like $TF_{diff,top}^*$ curves.

For medium Ra ($= 1000$) with fast reaction ($Da = 1000$), as we have more Da , the rate of reaction is higher. By comparing the base case with the fractured cases for $Da = 1000$ in Fig. 2(a), we see TF_{top}^* for fractured cases are higher than the base case. This is related to the existence of the fracture which can provide a place where the reaction process may occur, and therefore, more dissolution of CO_2 leads to having more TF_{top}^* . To measure the amount of reaction in the domain, we can check the decrease of average concentration of $CaCO_3$ (corresponds to the change of mass in the domain) to see the amount of dissolution of $CaCO_3$ in reaction with CO_2 . Fig. 5 illustrates the variation of the average concentration of $CaCO_3$ for the slow and fast reactive cases. In this figure, we can see that the difference between the cases starts from the first stage of mixing ($t^* = 0.0045$), and it is obvious that for medium Ra ($= 1000$) when there is a low reaction rate ($Da = 100$) in the domain, the base case has more dissolution due to having more entering TF_{top} of CO_2 rather than the fracture cases. But when there is a high reaction rate ($Da = 1000$) in the domain, the fracture cases have more dissolution than the base case because of having a place (fractures), which helps the reaction

process. To illustrate the development of fingers of dissolved CO_2 , in Fig. 3 it is perfectly evident that for fast reaction cases ($Da = 1000$), the fracture helps the dissolution process through the fracture (specifically in HF1 and HF2 at $t^* = 0.01$ when fingers reach the fracture), and for slow reaction cases ($Da = 100$), longer fingers can be seen in reactive base case which leads to having more dissolution rather than HF cases. In brief, for medium Ra , when there is a slow reaction, the existence of horizontal fracture causes the domain to capture the lower total flux of CO_2 . Also, when there is a fast reaction, the horizontal fracture causes the domain to capture a higher amount of total flux of CO_2 .

In Fig. 2(b), we have high $Ra (= 4000)$, which represents a higher convective flow. Therefore, there is higher natural convection, and as it is shown the bar chart, regardless of the value of Da , TF^*_{top} are almost the same due to convective mixing. However, there is a slight difference in non-reactive cases and the cases with low reaction. Thus, If the Ra is high, especially for fast reactions, the horizontal fractures will not affect our estimation of the total flux of CO_2 that can be stored in the domain.

Fig. 3. Time integration of the dimensionless total flux of CO_2 at the top boundary (TF^*_{top}) for both homogeneous unfractured case and horizontal fractured cases: medium convection flow ($Ra = 1000$) at left and high convection flow ($Ra=4000$) at right.

Fig. 4. Concentration distribution of dissolved CO_2 for unfractured homogeneous and HF scenarios at $t^* = 0.01$. The black arrows and red arrows represent convective and diffusive fluxes respectively.

Fig. 5. Time variation of the dimensionless fluxes of CO₂ at the top boundary for the HF scenario: (a) total convective flux and (b) total diffusive flux ($Ra = 1000$ and $Da = 0, 100$).

Fig. 6. Time variation of the average concentration of CaCO₃ in the domain: low reaction rate (at left) and high reaction rate (at right), for the HF scenario.

3.2. Vertical Fracture (VF)

In the present section, we explore vertical fractured (VF) scenario for three cases of different positions of vertical fracture, as mentioned in Table 2 similar to the cases of HF scenario. Fig. 6 shows the results of the dimensionless total flux of CO₂ entering the domain during $t^* = 0.015$. To begin with, like the horizontal fracture, TF^*_{top} for reactive cases are more than the non-reactive cases because of the reasons noted in the previous section. For medium Ra ($= 1000$) in Fig. 6(a) considering non-reactive cases ($Da = 0$), as one can observe, TF^*_{top} of the base case is higher than the fractured cases. But for reactive cases ($Da = 100$ and 1000)

it is vice versa, and especially when there is a fast dissolution ($Da = 1000$), TF_{top}^* of the base case is lower than the fractured cases. This can be related to the fact that for non-reactive cases, the presence of fracture seems to be an obstacle for the convective flow, and during mixing convection, because of the upward flow of freshwater through the vertical fracture (Kim et al., 2019), it would cause to be lower entering flux of dissolved CO_2 . Nonetheless, for reactive cases, the presence of fracture facilitates the reaction process and provides a location where the reaction can take place. As a result, there would be more precipitation of CO_2 with minerals. This increases the concentration gradient and lead to more dissolved CO_2 flux to enter from the top boundary. In Fig. 6(b), almost the same results of high Ra ($= 4000$) are shown, and we see that the difference between the fractured cases and the base case for each Da are not noticeable as medium Ra cases, because of the high natural mixing convection. Since the CO_2 is injected sinusoidally through the top boundary, the coincide of dense plume flow with the fracture is by chance, and we cannot observe any relation between the different VF cases, as they have different positions and do not confront a determined plume of CO_2 .

Fig. 7 presents the concentration distribution of dissolved CO_2 at $t^* = 0.01$ for the base case and VF scenario for non-reactive and reactive cases. For the non-reactive cases, the restrictive effect of the vertical fracture on the finger development is clear. For instance, in cases VF1 and VF3, we can see the fracture hinders the left and right fingers respectively to growth due to the upward flow of freshwater. As mentioned above, because of sinusoidal injected CO_2 , the plume flow through the fracture is accidental, and for example in Fig. 7 for VF1 when $Da = 1000$, we can see the generation of a finger through the fracture, so it explains why in Fig. 6a, TF_{top}^* for VF1 at fast-reactive case, is higher than the other fractured cases.

Fig. 8 shows the variation of convective and diffusive total fluxes at the top boundary versus t^* at $Ra = 1000$ and at $Da = 0$ and 100 for the base case and VF2. In both of the convective

and diffusive total fluxes at the first stage of mixing ($t^* = 0.006$), we see a higher maximum of $TF^*_{adv,top}$ and $TF^*_{diff,top}$ for reactive and non-reactive cases of VF2, since the CO_2 plumes migrate downward across the vertical fracture at this period. However, after the first stage of mixing for both of the convective and diffusive total fluxes, we see the same trend as horizontal fracture depicted in Fig. 4.

Fig. 7. Time integration of the dimensionless total flux of CO_2 at the top boundary (TF^*_{top}) for the VF scenario: medium convection flow ($Ra = 1000$) at left and high convection flow ($Ra=4000$) at right.

Fig. 8. Concentration distribution of dissolved CO_2 for homogeneous and VF scenario at $t^* = 0.01$. In all cases $Ra = 1000$. The black arrows and red arrows represent convective flux and diffusive flux respectively.

Fig. 9. Time variation of the dimensionless fluxes of CO_2 at the top boundary for the VF scenario: (a) total convective flux and (b) total diffusive flux ($Ra = 1000$ and $Da = 0, 100$).

3.3. Inclined Fracture (IF)

This section considers the inclined fractured scenario for three different cases. It examines the effect of fracture angle on the dissolution of injected CO₂ in reactive porous media for low angle (20°), medium angle (45°), and high angle (70°) fracture. Fig. 9 represents the dimensionless total flux of CO₂ entering the domain during $t^* = 0.015$. Comparing the base case and low angle case, we can see for medium Ra ($= 1000$), no matter of the value of Da (or the amount of rate of reaction), TF^*_{top} of the base case is higher than TF^*_{top} of IF20 case, and this is also true for high Ra ($= 4000$) with lower intensity as there is higher convective mixture. This can be attributed to the fact that low angle fracture has almost the same features as a horizontal fracture; thus, it restricts the entering flow of dissolved CO₂. Moreover, as depicted in Fig. 10, which shows the concentration distribution of dissolved CO₂ at $t^* = 0.01$, for all Da of the IF20 case, it is clear that the low angle fracture, like the horizontal fracture, inhibits the growth of fingers.

In Fig. 9(a), the case of high angle fracture (IF70) has the highest value of TF^*_{top} in comparison with the other cases when there is a reaction in the domain (especially fast reaction). In this case, as depicted in Fig. 10, fracture helps the freshwater to transfer upward in the domain, and it causes the merging and mixture of the plume fingers of dissolved CO₂ over the domain. By having a fast reaction, there is more dissolution of CO₂; therefore, the total entering flux of CO₂ increases. The case of medium angle fracture (IF45) seems to have a restrictive role for entering flow of dissolved CO₂ and in addition to be a pathway for the upward flow of freshwater; thus, it has a combined feature of IF20 and IF70. For high Ra ($= 4000$) in Fig. 9(b), as noted before, a very slight difference can be seen between different cases, and they have almost the same value of TF^*_{top} like other scenarios.

Figs. 11(a and b) show the variation of both convective and diffusive total fluxes at the top boundary versus t^* for $Ra = 1000$. First of all, in these two figures, it is clear that the fluxes

of reactive cases are higher than the non-reactive cases after the first stage of mixing ($t^* = 0.006$), and have the same trend as previous scenarios. In the first stage of mixing, as one can observe, high angle fracture case has the highest value (especially for convective flux), and low angle fracture case has the lowest value. The reason is that IF70 at the first stage is the pathway for dissolved CO_2 and it facilitates the convective flow. However, IF20 at the first stage is like a horizontal fracture, and it inhibits the CO_2 plumes. Figs. 11(c and d) show the variation of both convective and diffusive total fluxes through the fracture ($\text{TF}^*_{\text{adv},f}$ and $\text{TF}^*_{\text{diff},f}$) versus t^* at $Ra = 1000$. Here also, we can see at the end of the mixing, the fluxes through the fracture of reactive cases are higher than the non-reactive cases because of the higher dissolution of CO_2 . In Fig. 11d for diffusive flux through the fracture, we see the same trend as the fluxes at the top boundary. However, in Fig. 11c due to the interaction between different tendencies of inclined fracture in restricting the growth of CO_2 plumes, increasing mixing convection, and being a pathway for upward transport of freshwater, there is no particular trend for curves of convective flux through the fracture.

Fig. 10. Time integration of the dimensionless total flux of CO_2 at the top boundary (TF^*_{top}) for the inclined fractured scenario: medium convection flow ($Ra = 1000$) at left and high convection flow ($Ra=4000$) at right.

Fig. 12. Time variation of dimensionless convective total flux at the top boundary (a), diffusive total flux at the top boundary (b), convective total flux through the fracture (c), and diffusive total flux through the fracture (d).

3.4. Network of Fractures (NF)

The effect of different levels of fracture network (referred to as fracture density) on convective-reactive transport is investigated in this section. We consider three cases as three different levels of orthogonal fractures for the network of fracture (NF) scenario, as defined in Table 2. Like all the previous scenarios, the dimensionless total flux of CO_2 entering the domain during $t^* = 0.015$ for different cases of NF scenario are represented in Fig. 12. Comparing the base case with the cases of the NF scenario for medium convective flow ($Ra = 1000$) in Fig. 12a, we can see that for the fast-reactive cases ($Da = 1000$) the total entering flux of dissolved CO_2 from the top boundary are getting higher by increasing the level of the

orthogonal fractures (fracture density), and this is noticeable even if for high Ra in Fig. 12b. The reason is that as the level of orthogonal fractures increase, there would be more fractures to help the mixing and to provide a place where the reaction process can occur, and more dissolution of CO_2 leads to greater TF^*_{top} . This is almost true for slow-reactive cases ($Da = 100$) but in a lower intensity due to the lower dissolution. Fig. 13 shows the concentration distribution of dissolved CO_2 at $t^* = 0.01$. It is clear for the reactive cases, increasing the level of fractures causes the plumes of dissolved CO_2 to distribute over the domain, and we can see that the fractures behave as pathways that help the dissolution.

As noted before, to find out the amount of reaction occurring in the domain, we can measure the decrease in the average concentration of $CaCO_3$. Fig. 14 presents the variation of the average concentration of $CaCO_3$ in the domain for the different convective-reactive flow of NF scenario. Figs. 14(a and d) we have the lowest and highest loss of $CaCO_3$ concentration respectively as expected, since for the first case, there is low reaction and medium natural convection, and for the second case, there is high reaction and high natural convection. As one can observe, only in Fig. 14b, in which $Ra = 1000$ and $Da = 1000$, is there a noticeable difference between the curves of different cases, and for other combinations of Ra and Da we cannot distinguish them easily. The case with slow reaction ($Da = 100$) does not have a large impact on the variation of $CaCO_3$ concentration, since there is not enough dissolution of dissolved CO_2 in reaction with $CaCO_3$, and it can be confirmed by observing the low-reactive cases of Fig. 12. Furthermore, high natural convection ($Ra = 4000$) leads to having more convective mixing, and as shown in Fig. 14 (c and d), different cases of NF scenario have almost the same amount of dissolution. In Fig. 14b as expected from the discussion above for the total entering flux of CO_2 , the loss of $CaCO_3$ concentration for the cases NF2 and NF3 are more than NF1, and also it is more than the base case, and we can see the higher fracture density results in more mixing and consequently more reaction.

Fig. 13. Time integration of the dimensionless total flux of CO₂ at the top boundary (TF^*_{top}) for the network of fractures scenario: medium convection flow ($Ra = 1000$) at left and high convection flow ($Ra=4000$) at right.

3.5. Outcrop Analogues

In this section, we examine how fractures in rocks control the migration and trapping of injected dissolved CO_2 in deep geological formations. For this aim, an outcrop analogue of volcanic basalt rocks in Lebanon is considered, and it contains various types of fractures with different sizes of aperture as shown in Fig. 15. We have selected a rectangle as a reservoir with a horizontal width of 100 (m) and a height of 50 (m), which here is referred to as real case. For simplicity, we assume that there are big (2 cm), medium (1 cm), and small (0.5 cm) aperture sizes of fractures. The initial and boundary conditions of the real case are the same as the conceptual model, and the physical parameters are summarized in Table 3. To determine the effect of fractures on the migration behavior of dissolved CO_2 plume and to evaluate the reactive-convective mixing, the homogeneous and fractured domains are

simulated for different rates of reactions. For the fractured domain, we consider two cases. In the first one (case 1), we neglect the thin fractures to reduce model complexity; thus exclusively, the biggest fractures are included. In the second one (case 2) we consider fractures with all sizes of aperture.

The concentration distribution of dissolved CO_2 in the homogeneous case and two fractured cases for different rates of reaction at $t^* = 0.315$ (the equivalent of 10 years) are presented in Fig. 16. In each case, we explore the results for no reaction ($k_r a_v = 0$), slow reaction ($k_r a_v = 5 \times 10^{-10} \text{ m}^3 \cdot \text{s}^{-1} \cdot \text{mol}^{-1}$), and fast reaction ($k_r a_v = 5 \times 10^{-9} \text{ m}^3 \cdot \text{s}^{-1} \cdot \text{mol}^{-1}$). First of all, it is obvious that as the rate of reaction increases in the domain, the dissolved CO_2 plume over the domain decreases due to the enhancement of the dissolution of CO_2 in reaction with CaCO_3 . In Fig. 16, we can clearly see that the rate of reaction affects the amount of dissolved CO_2 distributed in each case. Also, we observe that the heterogeneity leads to an increase of the CO_2 plume in the surface area. Comparing case 1 and case 2 of the fractured cases shows that adding more different types of fractures helps the spreading of dissolved CO_2 in the domain, and the heterogeneity helps the spreading of dissolved CO_2 by passing the plume flow through the fracture. In case 2 the existence of thin fractures (Other than the ones with big aperture) causes the dissolved CO_2 to distribute more over the domain. Moreover, the domain is more sensitive to heterogeneity when there is no reaction, and for a higher rate of reaction, we can see that the spreading of the dissolved CO_2 through the fractures is less. For instance, for the high-reactive domain, heterogeneity has the lowest effect on CO_2 distribution.

Fig. 17 illustrates the dimensionless total flux of CO_2 entering the domain from the top boundary (TF_{top}^*) during $t^* = 0.315$. To begin with, the fractured cases rather than homogeneous case, and also, the case with higher heterogeneity (case 2) rather than the case with lower heterogeneity (case 1) have higher TF_{top}^* , since the fractures help the dissolved

CO₂ to spread over the domain generally. As a result, the need for entering total flux will increase in the domain. In the homogeneous case, like the conceptual model, the values of TF^*_{top} for the fast-reactive domain is more than the slow-reactive domain, and we see as the reaction rate increases, the total entering flux of CO₂ gets higher. As noted before, this is because the reaction between CO₂ and CaCO₃ will increase the gradient of CO₂ concentration at the top boundary, and consequently, there would be an increase in the rate of entering total flux of CO₂. However, we cannot see this trend in the two other fractured cases in Fig. 17. This can be attributed to the fact that some fractures in the domain may have a restrictive role in spreading the flow of dissolved CO₂, and for different reaction rates in fractured cases, the dissolved CO₂ plumes can be hindered in the face with some fractures in their growth pathway. Furthermore, this figure shows that the effect of the reaction is more when we have all types of fractures (Case 2) than when we have just the fractures with big aperture (Case 1); in other words, the case with higher heterogeneity is more sensitive to the reaction rate.

Fig. 18 represents the variation of the average concentration of CaCO₃ for the slow and fast reactive cases. It is clear that for all the cases when there is a fast reaction, the domain has more dissolution of CaCO₃, and the average concentration of CaCO₃ decreases more in comparison to the slow-reactive cases. The mentioned point that the cases with higher heterogeneity are more sensitive to the reaction rate can be seen in this figure, and the difference between the slow reaction and fast reaction curves is increasing from homogeneous case to the fractured-case 2.

Fig. 16. Photograph showing the outcrop of volcanic basalt rocks in Lebanon. Three sizes of aperture for the fractures are considered in this case: The black, red, and yellow lines represent fractures with large (2 cm), medium (1 cm), and small (0.5 cm) aperture, respectively.

Table 3. Physical parameters used for the real case.

Parameter	Variable	Value
Length	L	100 (m)
Height	H	50 (m)
Density of fresh-water	ρ_0	1000 (kg/m ³)
Density of CO ₂ -water at the top boundary	ρ_s	1010 (kg/m ³)
Concentration at the top boundary	c_b	$1 + A \cdot \sin(2\pi x / \lambda)$
Amplitude	A	0.01 [-]
Wavelength of sinusoidal perturbation	λ	1/12 (m)
Porosity of the medium	ε_m	0.1 [-]
Porosity of fracture	ε_f	0.3 [-]
Diffusion coefficient	D_m	1×10^{-9} (m ² /s)
Dynamic viscosity	μ	5×10^{-4} (kg/(m·s))
Gravitational acceleration	G	9.8 (m/s ²)
Pressure at the top boundary	P_b	10 (MPa)
longitudinal dispersivity	α_L	1 (m)
transverse dispersivity	α_T	0.1 (m)
Fracture dispersivity	α_F	1 (m)
Intrinsic permeability of the medium	k_m	1×10^{-13} (m ²)
Intrinsic permeability of fracture	k_f	1×10^{-9} (m ²)
Fracture aperture	$2b$	0.5, 1, 2 (cm)
Rate of reaction	$k_r a_v$	0, 5×10^{-10} , 5×10^{-9} (m ³ /(s.mol))

4. Conclusion

The geological sequestration of CO_2 is the most efficient technique for reducing carbon emissions to the atmosphere. A crucial issue in improving this technique, for safe implementations and in assessing its ecological and geological impacts relies on a good understanding of the fate of CO_2 in geological formations. Mainly the carbonic acid, resulting from CO_2 , is controlled by the density-driven convection (DDC) and dissolution processes. Fractures and faults can be found worldwide in several storage reservoirs/aquifers. In certain cases, fractures are stimulated, by hydraulic fracturing, in order to improve the storage capacity of aquifers. The effect of fractures on DDC during CO_2 sequestration has been widely discussed in the literature, but previous works neglect the effect of dissolution and reaction. This work aims at addressing this gap by evaluating the effect of fractures on the coupled processes of DDC and mineral dissolution. Our methodology is based on numerical simulations that are commonly used to investigate CO_2 for practical and theoretical purposes. A COMSOL model is developed to perform the simulation. Appropriate numerical

techniques are selected to reduce the computational requirements while maintaining high accuracy. The model is first applied to a synthetic domain with hypothetical fractured configurations. The convective flow is controlled by the Rayleigh number while the dissolution rate can be represented by the Damköhler number. We explore different combinations of these non-dimensional parameters to evaluate the coupled effects of convection and mineral dissolution on the total flux of CO_2 , under different configurations of fracture characteristics and topology. For more representative geology, we apply the methodology on a large-scale outcrop of a volcanic basalt rock formation in Lebanon. Based on outcrop analogy we evaluate the capacity of fractured volcanic basalt rocks in trapping CO_2 . The main findings of each scenario are summarized separately in the following:

- Horizontal fracture scenario: For medium convective flow, when the reactions are fast, by neglecting horizontal fractures, the entering total flux of CO_2 is underestimated, and if the reaction is slow, neglecting horizontal fracture will lead to overestimation of the total flux of CO_2 . For high convective flow, neglecting horizontal fractures will not affect the estimation of the total flux of CO_2 that can be stored in the domain, especially for fast reactions. For slow reactions, the total flux of CO_2 is slightly sensitive to the fractures. Also, it was found that horizontal fracture can help the mixing by convection and reaction processes in the domain, it can play a restrictive role in entering dissolved CO_2 , and when the position of the horizontal fracture is not near the top surface, it has less influence on the entering flux. Moreover, for all cases, reactions enhance the capacity of the domain in capturing CO_2 .
- Vertical fracture scenario: For medium convective flow, when we have a non-reactive domain, neglecting vertical fracture will lead to overestimation of the total flux of CO_2 , and when we have a reaction in the domain (especially for fast reaction),

neglecting vertical fracture will lead to underestimation of the total flux of CO_2 . And high convective flow, we have the same results but with less intensity. Furthermore, it was observed that the vertical fractures could hinder the fingers from growing due to the upward flow of freshwater.

- Inclined fracture scenario: Regardless of the rate of the reaction, ignoring the inclined fracture with a low angle leads to an overestimation of the total flux of CO_2 , no matter the rate of the reaction. Also, ignoring the inclined fracture with a high angle leads to an underestimation of the total flux of CO_2 , especially for the fast-reaction cases. In general, we saw that the low angle fracture acts like horizontal fracture which inhibits the growth of fingers, and the high angle fracture acts like vertical fracture which helps the freshwater to transfer upward in the domain, and eventually, the medium angle of fracture appears to have a combination of these effects.
- Network of fractures scenario: By increasing the level of the orthogonal fractures, the total entering flux of dissolved CO_2 from the top surface is higher, and the more the rate of reaction, the stronger this effect. This is true for both medium and high convective flow. Network of fractures behave as pathways that help the dissolution of dissolved CO_2 , and higher fracture density causes the plumes of dissolved CO_2 to distribute more evenly throughout the domain especially for high-reactive cases.
- Outcrop analogs (Real case): For the case of a realistic fracture network, containing fractures with different apertures, lengths and separations, for all the rates of reaction, we saw that ignoring heterogeneity results in an underestimation of the storage capacity of the total entering flux of CO_2 . It is found that heterogeneity helps the spreading of dissolved CO_2 by passing the plume flow through the fracture and leads to an increase of the CO_2 plume in the surface area. This effect will be higher when

there is less reaction in the domain; in other words, the domain is more sensitive to heterogeneity when there is no reaction, and for a higher rate of reaction, the spreading of the dissolved CO₂ through the fractures is less.

The present work contributes to a better understanding of the impact of fractures on the mechanisms of CO₂ trapping. However, there are many uncertainties in the input parameters for both static geological modeling and dynamic flow modeling. Future work should be directed to evaluation of the uncertainties related to fractures on model outputs. The effects of more complex/realistic geochemical reactions are worthy of investigation. Extension to 3D domain and fractures could be an interesting direction for future research. An important issue is also the influence of mineral dissolution on the fracture characteristics, which is neglected in this work.
