Abstract.—The many Early Ordovician crinoid discoveries over the past 30 years signal a largely undocumented crinoid radiation totalling a more than five-fold increase in diversity, an important event in crinoid history. Camerate, cladid, and disparid clades had emerged by the Late Tremadocian Series, early during this time. These finds provide data for character analysis in phylogenetic reconstructions, particularly those aimed at identifying early branching within the crinoid tree. Early Ordovician crinoids comprised among the earliest-known benthic invertebrates to exploit food resources high above the substrate. Significantly, they were also among the largest known faunal elements during this time. A tentative listing of Early Ordovician crinoids and their distributions is provided; this compendium is subdivided into time slices with Laurentian and global stratigraphic units.

Introduction

Prolific, diverse, and abundant Late Ordovician crinoid faunas have long implied an extensive but largely unknown prior record. Just a handful of Early Ordovician taxa were described by the end of the 20th century (Ubaghs, 1969, 1983; Strimple and McGinnis, 1972; Donovan and Cope, 1989). Dozens of new Early Ordovician taxa have been discovered over the past 30 years (Table 1). Formal study of these, and their significance in understanding crinoid origins and affinities, are works in progress. Long fieldwork, coupled with difficult preparation, has slowed the process. The Tremadocian discoveries are largely described (Guensburg and Sprinkle, 2003; 2009; Guensburg, 2012; Guensburg et al., 2019). A majority of the Floian taxa are not formally described but have been assigned to subclass and, where possible, lower rank taxa. Enough is now known to provide a preliminary accounting of this largely unrecognized radiation of Early Ordovician crinoids.

An important consideration for this study concerns dating of Early Ordovician rocks through improved global biostratigraphic control. A more finely resolved framework for early crinoid occurrences based upon trilobite biostratigraphy in the Great Basin, western United States, is available (Adrain et al., 2009; Adrain et al., 2014). Most critically, stage boundaries for the crinoid-bearing Early Ordovician Ibexian Series in Laurentia have been shifted upward relative to the global standard (Walker et al., 2018). In ascending order, these stages are the Stairsian, Tulean, and Blackhillsian. The new data indicate the entire Stairsian stage and lower 80% of Tulean stage are equivalent to the upper Tremadocian stage of the global standard (Walker et al., 2018). The Floian in Laurentia includes the uppermost Tulean and all of the Blackhillsian stages. The distribution of Early Ordovician crinoids with adjusted stratigraphic data are provided in Table 1.

Materials and repositories.—Figured specimens are housed in the Field Museum (PE), Chicago, Illinois, Idaho Museum of Natural History (IMNH IP-), Pocatello, Idaho, Non-vertebrate Paleontology Laboratory (NPL ____TX__), University of Texas, Austin, Texas, Palaeontological Collections (UCBL-FSL), Lyon 1 University, Villeurbanne, France, and Paleontology Repository (SUI), University of Iowa, Iowa City, Iowa.

Early crinoid morphology and establishment of major crinoid clades

Stratigraphic and preliminary phylogenetic evaluation make it possible to hypothesize a sequence of events during which characters first appear within different crinoid lineages. These provide evidence for evaluating the likelihood as to whether similarity among these lineages reflects homology or homoplasy. Here, we apply a broad-brush approach simply to highlight timing of intermediate morphologies that are precursors to those that characterize major crinoid clades, rather than discuss individual characters in detail. We are aware of the shortcomings of this approach, and the need for formal phylogenetic analysis, but this process awaits more formal descriptive data.

Tremadocian diversification of major clades.—The earliest-known crinoids appear during the upper portion of the Tremadocian Series (Stairsian Stage of Laurentia) (Adrain et al., 2014), an estimated 481 Myr, and four million years after the Cambro-Ordovician boundary (Walker et al., 2018). The transitional nature of these fossils stands out.

In many ways, taxa of this assemblage exhibit more commonality than later faunas. Stalks are pentameric and calyces have fixed interbrachial plate fields. In particular, arm construction is similar, and includes internal calcified floor plates with podial pores, brachials with secondary aboral grooves, and two-tiered cover plates (Guensburg, 2012; Guensburg et al., 2019). Tremadocian crinoid axial arm constructs (floor, cover plates) resemble certain non-blastozoan pentaradiate echinoderms of the Cambrian rather than later crinoids. All earliest-known taxa (*Apektocrinus*, *Glenocrinus*, *Titanocrinus*) possess lateral plate fields in their arms. None of the Tremadocian crinoids expresses pinnules.

The cup construction of earliest camerate-like taxa, called protocrinoids (*Glenocrinus*, *Titanocrinus*), differs from other Tremadocian taxa. The mid-cup consists of many non-differentiated plates that separate ray plating from the cup base circlet. In addition, the posterior interrady is wide and extends to the stalk, where a gap plate (or plates) interrupts the cup base circlet. This information has been used to propose the Dual Reference Homology System (Guensburg and Sprinkle, 2003), a modification of the long-used Carpenter (1879) system.

Diversification into clades familiar to paleontologists today had begun but data indicating how these are interrelated is scanty and perplexing. Protocrinoids and other taxa express expanded tegmens without articulating cover plates, a camerate character. Assignment of cladid-like forms is based upon differentiated sub-C-ray “anal” plating. Earliest disparid-like and later early camerate-like taxa express a posterior plate series projecting from the C-ray and extending up an

anal sac or tegmen (see Guensburg, 2012; Gahn, 2015). Data from as yet undescribed taxa are needed.

Floian and first typical Paleozoic crinoids.—Early Floian taxa express more organized cup plating but some retain Tremadocian-like arm morphology (Fig. 2). Camerate, cladid, and disparid morphology typical of Middle and Late Ordovician crinoids was present by the end of the Floian (Blackhillsian Stage of Laurentia), approximately 470 Myr (Adrain et al., 2009) (Walker et al., 2018). Stalks show the earliest evidence of holomerism, which evolved independently in each clade. Cup plating becomes more regular and standardized (Donovan and Cope, 1989). Arms assume crownward morphology, that is, without floor or lateral plating, which also evolved independently in each clade. Latest camerates in this sequence (*Celtocrinus*, *Proexenocrinus*) exhibit pinnulate arms and ray branching at fixed primibrachial three and holomeric columnals, but surprisingly, one taxon expresses floor plates in pinnules (*Proxenosocrinus*). Disparids possess fewer fixed brachial, interbrachial and posterior interray plates (*Inyocrinus*, *Ramseyocrinus*). Arms become free above the radials (“compound radial” terminology is not accepted here), and an elongate anal sac characterizes most taxa. Cladids include a number of taxa in which cup plating is more regular and interbrachial plate fields are small or absent (*Compagicrinus*, *Elpasocrinus*). The late Floian (Blackhillsian Stage) cladid record is diverse and includes dendrocrinid-like forms, hybocrinids, two other monocyclic forms, one with branched arms, a porocrinid-like taxon, and another dicyclic form with atomous arms.

A curious aspect of many early crinoids is their large size relative to other faunal elements such as brachiopods and nearly all trilobites (Figs. 1, 2). Crowns can be several centimeters in height, and stalks 10s of centimeters in length, with a maximum known stalk length of over 60 cm. Along with a few poriferans, nautiloid cephalopods, crinoids and a few blastozoans represent the largest-known and most common faunal elements in these Laurentian Tremadocian occurrences. By comparison, associated brachiopod taxa are no more than 1 cm across.

Early crinoid diversification in the context of the Ordovician Radiation

There is a diversity of opinions as to how to characterize the marine invertebrate radiation during the Ordovician (most recently Servais and Harper, 2018; Stigall et al., 2019; Edwards, 2019). Crinoids first appear during the Tremadocian Series, coincident with radiations of other characteristic Paleozoic

faunal elements such as graptolites, chitinozoans, gastropods, and cephalopods (Stigall et al., 2019) during the initial phase of the Ordovician Radiation. This radiation took place prior to the appearance of characteristic Paleozoic faunal elements such as bryozoans, rugose and tabulate anthozoans, and many brachiopods.

It is important to recognize the scale of the previously unrecognized early crinoid component of the Ordovician Radiation. The present list (Table 1) shows a more than five-fold increase in previously known Early Ordovician crinoid diversity, with most of the increase during the Floian. This represents one of the most significant diversification events in crinoid history.

The expanded crinoid record invites inquiry into when and how the crinoid clade might have originated. Probabilistic modelling indicates a Cambrian origin (Wright, 2018). Tremadocian crinoids express characters found among early non-blastozoan pentaradiate echinoderms of the Cambrian (above), suggesting proximity to the crinoid node (Guensburg, 2012). In our view, a diagnostic crinoid level of organization requires at least two apomorphies: “true arms” bearing left and right somatocoel extensions (sensu David and Mooi, 1999; Guensburg et al., 2019), and a pentameric stalk.

It is a narrow morphological gap from this “minimalist” diagnosis of a crinoid to Tremadocian crinoids, and a differentiated ray plate series and calyx base circlet could have co-evolved during this process. With underlying soft-tissue anatomy already in place, it can be postulated that functional requirements produced rapid evolution of these traits. The four million years at the base of the Ordovician for which we have no crinoids yet may have been sufficient for these changes to have evolved from pre-crinoid ancestry, but it is also likely that even earlier taxa expressing some nascent features of the crinoid clade existed in the Cambrian, such as in *Camptostroma* with its short “proto-arms” (Durham, 1966), and possibly the enigmatic *Echmatocrinus* (see Sprinkle and Collins, 2011).

Paleobiogeography of Early Ordovician crinoid diversification

Early Ordovician crinoids ranged across a variety of paleoenvironmental settings, from siliciclastic-dominated mobile substrates in high latitude Gondwana and Avalonia to largely carbonate-dominated mobile and hard substrate settings of equatorial Laurentia (Blakey, 2020). However, intensive fieldwork in several regions of the globe produced different results in terms of diversity and timing of origination (Guensburg and Sprinkle, 1992; Lefebvre and Fatka, 2003; Lefebvre

et al., 2013; inter alia). Laurentian localities yield a high diversity fauna, including the earliest-known crinoids. The Great Basin of the western United States has been particularly productive for Laurentian crinoids (Guensburg and Sprinkle, 2003, 2009; Guensburg, 2012; Guensburg et al., 2019). Avalonian/Gondwanan localities produce many echinoderms, including many stalked blastozoans, but few crinoids (Lefebvre et al., 2013).

Regional, but temporally persistent environmental conditions, accompanied the Early Ordovician crinoid radiation in Laurentia. First, geochemical proxies indicate higher oxygen levels in widespread shelfal seas during this time (Edwards, 2019). Oxygen levels were enhanced by cyanobacterial respiration emanating from microbial buildups, also common in this setting. Next, lithified substrates or hardgrounds developing on the microbial buildups and associated intraclastic limestones (flat pebble conglomerates) provided expansive living space (Church, 1974; Wilson et al., 1992; Guensburg and Sprinkle, 1992; Datillo, 1993; Sprinkle and Guensburg, 1995). Direct evidence shows that early crinoids exploited these surfaces using polyplated encrusting-type holdfasts.
