Keywords: prokaryotic community composition, 16S rRNA, amplicon sequence variants,
natural iron fertilization, Southern Ocean

25 Abstract

Natural iron (Fe) fertilization sustains phytoplankton blooms above the Kerguelen plateau (Indian sector of the Southern Ocean) within otherwise low productive off-plateau waters. In early spring and summer, these diatom-dominated blooms are associated with distinct heterotrophic prokaryotic communities, but whether a structuring effect extends to the post-bloom period has thus far not been investigated. To address this question, we carried out a detailed study of the prokaryotic community composition in the region of Kerguelen Island during late Austral summer (18 February to 27 March 2018; MOBYDICK project). Concentrations of chlorophyll *a* were seasonally low above the plateau (0.27-0.58 $\mu\text{g Chl } a \text{ L}^{-1}$) and in a similar range to those at the 3 off-plateau sites investigated (0.14-0.34 $\mu\text{g Chl } a \text{ L}^{-1}$), but we observed an accumulation of dissolved organic carbon and the build-up of heterotrophic prokaryotic biomass in Kerguelen plateau waters. Illumina sequencing of the 16S rRNA gene revealed that the total (DNA-based) and potentially active (RNA-based) prokaryotic communities were structured according to on- and off-plateau sites in the wind-mixed surface layer, in both the free-living ($< 0.8 \mu\text{m}$ size fraction) and particle-attached ($> 0.8 \mu\text{m}$ size fraction) size fractions. The Amplicon Sequence Variants (ASV) with significantly higher relative abundances in on-plateau surface waters as compared to off-plateau waters belonged to *Halieaceae* OM60 group, several *Flavobacteriaceae*, such as the NS5 marine group, *Aurantivirga* and *Ulvibacter*, *Rhodobacteraceae* *Loktanella*, *Saprospiraceae*, and the *Cryomorphaceae* NS10 marine group. ASVs with higher relative abundances in off-plateau waters belonged to the *Flavobacteriaceae* *Formosa*, the *Rhodobacteraceae* *Planktomarina* and the SAR11 clade. We discuss the potential abiotic and biotic drivers of community composition in late Austral summer and the ecological roles of abundant prokaryotic taxa in Kerguelen plateau waters.

50 1. Introduction

Heterotrophic prokaryotes contribute to the cycling of all elements in the ocean. Within the marine carbon cycle, they process roughly half of recent primary production with most of the organic carbon being respired (Ducklow *et al.*, 2007). This process mediates large fluxes of carbon and energy between autotrophic and heterotrophic microbial communities and has
55 important consequences for the potential storage of carbon in the ocean interior by the biological pump. Phytoplankton blooms are seasonally re-occurring events that stimulate prokaryotic and higher trophic level growth and metabolic activity. Diverse prokaryotes carry out the transformation of phytoplankton-derived organic matter (reviewed in Buchan *et al.*, (2014)) and the response is generally most pronounced a few weeks after the peak in
60 phytoplankton biomass (Bunse and Pinhassi, 2017). The observed succession in prokaryotic communities over the course of phytoplankton blooms (Teeling *et al.*, 2012) illustrates the dynamic interplay between the composition of organic matter released by phototrophs, the metabolic capabilities of individual taxa, and the potential species-specific phytoplankton-prokaryote associations.

65 Phytoplankton blooms induced by natural iron (Fe) fertilization provide excellent opportunities to investigate these processes in the otherwise low-productive Southern Ocean. The region east of Kerguelen Island harbors the largest phytoplankton blooms induced by natural Fe fertilization (Blain *et al.*, 2007). Prokaryotes contribute substantially to the transformation of phytoplankton-derived organic matter during early spring (November),
70 summer (January-February) and late summer (February-March) corresponding to the onset, peak and early decline, and the post-bloom phases in these perennially cold waters (Christaki *et al.*, 2020). These diatom-dominated blooms (Armand *et al.*, 2008; Lasbleiz *et al.*, 2016; Blain *et al.*, 2020) are associated with prokaryotic heterotrophic communities during early spring (Landa *et al.*, 2016) and in summer (West *et al.*, 2008; Obernosterer *et al.*, 2011) that

are distinct to those in surrounding low-productive waters. Onboard experiments have highlighted the role of diatom-derived organic matter in shaping prokaryotic community composition in spring (Landa *et al.*, 2016), and potential associations between diatom species and prokaryotic taxa has been identified as mechanism for the temporal structuring of microbial communities (Liu *et al.*, 2020). Observations from the post-bloom period when phytoplankton biomass has similar levels in on and off-plateau waters are thus far lacking, preventing to address the question on the effects Fe-fertilization on prokaryotic community composition at the seasonal scale in the Southern Ocean.

Numerous studies have described prokaryotic communities in different size-fractions, considered as free-living and particle-attached prokaryotes. The diversity and specific metabolic activity was shown to be higher in communities attached to particles as compared to free-living ones (Ghiglione *et al.*, 2007; Zhang *et al.*, 2007; Ortega-Retuerta *et al.*, 2013; Rieck *et al.*, 2015; Zhang *et al.*, 2020) or unchanged between size-fractions (Bachmann *et al.*, 2018). Observed differences have been associated to the respective lifestyle and metabolic capabilities. The composition, origin and quality of the particles was shown to have a strong influence on the associated prokaryotes (Zhang *et al.*, 2007; Ortega-Retuerta *et al.*, 2013; Rieck *et al.*, 2015). Therefore, exploring the free-living and particle-attached community structure can provide a better understanding of the processes influencing the prokaryotic diversity.

The present study was carried out as part of the project MOBYDICK (Marine Ecosystem Biodiversity and Dynamics of Carbon around Kerguelen: an integrated view) that aimed to provide a detailed picture of the diversity and role in the carbon cycling of biological communities of end-to-end food webs in contrasting nutrient regimes in the Southern Ocean. Our specific objective was to provide a description of the prokaryotic community composition. We considered the total (DNA-based) and potentially active (RNA-based) free-

100 living ($<0.8\ \mu\text{m}$) and particle-attached ($>0.8\ \mu\text{m}$) prokaryotic communities in the upper 300 m
water column. Our observations from late Austral summer, corresponding to roughly 2
months after the peak of the phytoplankton bloom, reveal distinct prokaryotic communities in
Kerguelen plateau surface waters as compared to off-plateau waters. We further identified the
prokaryotic taxa that explained the differences between on- and off- plateau waters, providing
105 insights to microbial processes occurring during post-bloom conditions in this fertilized
region of the Southern Ocean.

2. Material & Methods

2.1. Study area

110 Samples were collected in the region of Kerguelen Island in the Indian Sector of the Southern
Ocean in late Austral summer (MOBYDICK cruise; February 18 to March 27, 2018) (Fig. 1).
Four stations, identified as MOBYDICK-1 (M1), M2, M3 and M4 were sampled (Table 1).
Station M2 is located on the central Kerguelen plateau (overall depth 527 m), southeast of
Kerguelen Island, in naturally Fe-fertilized waters (Blain *et al.*, 2007). The other three stations
115 are located in off-plateau waters, east (M1) and southwest of Kerguelen Island (M3 and M4).
Station M3 is located in the polar frontal zone and stations M1, M2 and M4 are in Antarctic
waters, with station M1 being strongly influenced by the polar front (Pauthenet *et al.*, 2018).
The sampling period during the MOBYDICK cruise corresponded to roughly two months
after the seasonal maximum in chlorophyll *a* (Chl *a*) concentrations in on- and off-plateau
120 waters (Fig. S1). Station M2 was sampled three times (M2-1, M2-2 and M2-3) in an eight-day
interval, stations M3 (M3-1 and M3-3) and M4 (M4-1 and M4-2) were each sampled twice
with a 14-day interval and station M1 was visited once (Table 1).

2.2. Sample collection

125 Seawater samples were collected with 12 L Niskin bottles mounted on a rosette equipped with
a conductivity, temperature, depth sensor (Seabird SBE-911 plus CTD unit). Discrete samples
for concentrations of Chl *a* and dissolved organic carbon (DOC), and prokaryotic abundances
were taken at 10 to 12 depths in the upper 500m. The sampling depths for prokaryotic
community composition were chosen according to the CTD profiles with the aim to collect
130 seawater at the top and at the base of the surface mixed layer (Z_{ML}), in the transition layer,
and in deeper waters (Fig. S2). We used this strategy to obtain 2 samples from the Z_{ML} , focus
of our study, and to allow for a comparison of the surface water communities with those from
deeper layers. Seawater samples were collected at 10m, 60m, 125m and 300m at all sites and
visits, except for M2-1, where the following depths were sampled 10m, 50m, 100m and
135 300m. For clarity, the 50 m and 100m sampling depths at station M2-1 will be referred to 60
m and 125 m, respectively, in the description of the results and figures. The samples collected
at the two uppermost depths were within the Z_{ML} at all sites and visits, except for Station M1
where only the uppermost depth was within the shallow Z_{ML} (Table 1).

2.3. Concentration of Chl *a*

140 For the analysis of Chl *a* concentrations, 2.32 L of seawater were filtered through Whatman
GF/F filters and the filters were stored in liquid nitrogen until analysis in the laboratory.
Filters were extracted in 100% methanol, disrupted by sonication and clarified by GF/F
filtration after 2h. Samples were analysed within 24h using High Performance Liquid
Chromatography on an Agilent Technologies HPLC 1200 system equipped with a diode array
145 detector following (Ras *et al.*, 2008).

2.4. Dissolved organic carbon

The concentration of dissolved organic carbon (DOC) was determined in samples filtered through two combusted (450°C, 4h) GF/F filters. Subsamples of 10 mL (in triplicate) were transferred to pre-combusted glass ampoules and acidified with H₃PO₄ (final pH = 2). The sealed glass ampoules were stored in the dark at room temperature until analysis. DOC measurements were performed on a Shimadzu TOC-V-CSH (Benner and Strom, 1993). Prior to injection, DOC samples were sparged with CO₂ -free air for 6 min to remove inorganic carbon. Hundred µL of each of the sample replicates were injected in triplicate and the analytical precision was 2%. Standards were prepared with acetanilide. Consensus reference materials provided in sealed glass ampoules (<http://www.rsmas.miami.edu/groups/biogeochem/CRM.html>) was injected every 12 to 17 samples to insure stable operating conditions.

2.5. Enumeration of heterotrophic prokaryotes

For the enumeration of heterotrophic prokaryotes by flow cytometry, subsamples (1.44 mL) were fixed with glutaraldehyde grade I 25% (1% final concentration), and incubated for 30 min at 4 °C, then quick-frozen in liquid nitrogen and stored at -80 °C until analysis. Samples were collected from unfiltered seawater, considered as the bulk prokaryotic abundance, and from the < 0.8 µm size fraction, considered as the abundance of free-living prokaryotes.

Samples were thawed at room temperature. Counts were performed on a FACSCanto II flow cytometer (Becton Dickinson) equipped with 3 air-cooled lasers: blue (argon 488 nm), red (633 nm) and violet (407 nm). For the enumeration of non-autofluorescent cells, mainly heterotrophic prokaryotes, cells were stained with SYBR Green I (Invitrogen – Molecular Probes) at 0.025% (vol / vol) final concentration for 15 min at room temperature in the dark. Stained prokaryotic cells were discriminated and enumerated according to their right-angle

light scatter (SSC) and green fluorescence at 530/30 nm. In a plot of green versus red fluorescence, non-autofluorescent cells were distinguished from autofluorescent cells.

Fluorescent beads (1.002 μm ; Polysciences Europe) were systematically added to each

175 analyzed sample as internal standard. The cell abundance was determined from the flow rate, which was calculated with TruCount beads (BD biosciences).

2.6. Prokaryotic community composition

For the analysis of prokaryotic community composition, seawater was passed through a 60

180 μm nylon mesh and 6 L of seawater was filtered through 0.8 μm pore-size polycarbonate (PC)

membranes (47 mm diameter, Nuclepore, Whatman, Sigma Aldrich, St Louis, MO) to

retrieve the particle-attached ($>0.8 \mu\text{m}$) fraction. Prokaryotic cells in the $< 0.8 \mu\text{m}$ fraction

were concentrated on 0.22 μm cartridges (Sterivex™ Millipore, EMD, Billerica, MA) and

considered as free-living fraction. The filters were stored in sterile Eppendorf tubes (2 ml) and

185 the cartridges were sealed at both ends using parafilm. The filters and cartridges were stored

at -80°C until DNA and RNA extraction.

DNA and RNA extractions were performed simultaneously from the PC membranes (> 0.8

μm fraction) and the Sterivex™ cartridges ($> 0.2 \mu\text{m}$ fraction) respectively, using the AllPrep

Kit (Qiagen, Hilden, Germany) as described in (Liu *et al.*, 2019) with minor modifications.

190 The filter units were thawed and closed with a sterile pipette tip end at the outflow, 425 μl

lysis buffer were added per sample (40mM EDTA, 50mM Tris and 0.75 M sucrose) and three

freeze-thaw cycles were performed with liquid nitrogen and a water bath at 65°C .

Subsequently, 25 μl of freshly prepared lysozyme solution were added (2 mg ml^{-1} final

concentration), the filter units were placed in a rotary mixer and incubated at 37°C during 45

195 minutes, and then 8 μl of proteinase K solution (0.2 mg ml^{-1} final concentration) and sodium

dodecyl sulphate (SDS) (1%) were added and maintained at 55°C with gentle agitation every 10 min for 2 hrs.

To protect the RNA, 10 µl of β -mercaptoethanol were added to 1 ml of RLT plus buffer provided by the kit, 1,550 µl of this solution were added to each filter unit and mixed by

200 inversion. The lysate was recovered by using a sterile 5 ml syringe and loaded in three additions onto the DNA columns by centrifuging at 10 000g for 30 s. DNA and RNA purifications were performed following the manufacturer's guidelines (Qiagen, Germany).

The Invitrogen™ SuperScript™ VILO™ cDNA Synthesis Kit (Thermo Fisher Scientific Inc. Carlsbad, CA USA) was utilized to generate cDNA from the RNA extracts. Prior to the

205 reverse transcription, absence of DNA in the RNA extracts was verified by PCR test with general primer sets 341F (5'-CCTACGGGNGGCWGCAG) and 805R (5'-

GACTACHVGGGTATCTAATCC) (Herlemann *et al.*, 2011) for the prokaryotic 16S rRNA gene, followed by the examination of amplification products on 1% agarose gel

electrophoresis. If a specific band of 1 015 bp was observed the RNA extract was treated with

210 DNase.

The final PCR amplification of DNA and cDNA extracts was performed using the primers 515F-Y (5'-GTGYCAGCMGCCGCGG TAA) and 926R (5'-

CCGYCAATTYMTTTRAGTTT) that encompasses the V4 and V5 hypervariable regions of the 16S rDNA (Parada *et al.*, 2016). Triplicate 10 µl reaction mixtures contained 2 µg DNA,

215 5 µl KAPA2G Fast HotStart ReadyMix, 0.2 µM forward primer and 0.2 µM reverse primer.

PCR amplification was performed under the following conditions: an initial denaturation step of 95°C for 3 min, followed by 30 cycles of denaturation at 95°C for 45 s, annealing at 50°C for 45 s, and extension at 68°C for 90 s, and a final elongation step at 68°C for 5 minutes.

The presence of amplification products was confirmed by 1% agarose electrophoresis and
220 PCR triplicates were pooled and purified by gel-filtration through-Sephadex G-50 Super Fine
resin (Amersham Biosciences, Uppsala, Sweden). Then the purified samples were recovered
for sequencing. The 16S rRNA gene amplicons were sequenced via next generation
sequencing (Illumina MiSeq 2 × 250 bp chemistry on one flow-cell) at the platform GeT-
PlaGe Genotoul (Toulouse, France). Mock community DNA (LGC standards, UK) was used
225 as a standard for subsequent analyses and considered as a DNA sample for all treatments. In
total, 128 samples (32 DNA free-living, 32 DNA particle-attached, 32 cDNA free-living and
32 DNA particle-attached) were sequenced. After the sequencing one sample (cDNA free-
living at M2_1-60m) was discarded, due to low quality in the sequencing.

2.7. Sequence analysis

230 The samples obtained in the sequencing run were demultiplexed at the platform GeT-PlaGe
Genotoul (Toulouse, France). A total of 5,847,892 sequences were obtained. Processing
sequences was conducted with the DADA2 package for R version 1.10.1 (Callahan *et al.*,
2016a), following the pipeline by (Callahan *et al.*, 2016b). Amplicon sequence variants
(ASVs) were inferred through the high resolution DADA2 method (Callahan *et al.*, 2016a;
235 Callahan *et al.*, 2017). Primers were trimmed and the sequences were filtered based on their
quality using DADA2 (maxEE=2, truncQ=2). Forward reads with a length of 245 bp, reverse
reads with a length of 210 pb, and in total 4,253,969 reads were kept after quality filtering.
Error rates were estimated from the data, and inference of the sequence variants was made
from the pooled sequences from all the samples. The 1,059,953 unique forward sequences
240 and 1,619,348 reverse unique sequences were pooled to determine the sequence variants, then
the forward and reverse sequences were merged and chimeras were removed. We obtained
31, 227 unique ASVs. Taxonomy was assigned based on the SILVA database release 132 at
the highest taxonomic level possible (Quast *et al.*, 2013).

From the 5,847,892 reads we obtained a total of 14,204 ASVs for the 127 samples after
245 singletons removal. The number of reads per sample varied between 2,803 and 48,536. The
dataset was randomly subsampled to the lowest number of reads (2,803) per sample with
`rarefy_even_depth()` by Phyloseq R package version 1.26.1 (McMurdie and Holmes, 2013).
Ordinations were performed with both the complete and subsampled datasets, and the trends
observed were consistent for both datasets. To enable the comparison between samples with
250 different numbers of reads, we chose to carry out all analysis using the subsampled dataset.
After subsampling, 12,010 ASVs remained in the dataset.

From a total of 127 samples, the prokaryotic community composition was determined in the
free-living ($< 0.8 \mu\text{m}$) and in the particle-attached ($> 0.8 \mu\text{m}$) fractions. DNA-based samples
represent the total prokaryotic community and RNA-based samples were used to identify the
255 potentially active members of the community (Blazewicz *et al.*, 2013). Our sequencing data
provided access to 12,010 ASVs, of which 8,871 ASVs were obtained for the free-living
fraction and 8,838 ASVs for the particle-attached fraction, and 5,699 ASVs were shared
between these fractions.

In order to identify the prokaryotic taxa, the ASVs were compared against the SILVA
260 database release 132 at the highest taxonomic level possible (Quast *et al.*, 2013). The ASVs
with the same taxonomy at the order level were pooled for illustration of the relative
abundance in the samples. Sequences alignment was performed using MAFFT online service
for multiple sequence alignment (Kato *et al.*, 2019) and the phylogenetic tree was built using
PhyML 3.0 online program, based on the maximum likelihood method, with 100 bootstraps
265 and the HKY85 substitution model (Guindon *et al.*, 2010). The phylogenetic tree was
visualized with SeaView version 4.7 and saved as a rooted tree (Gouy *et al.*, 2010). The tree
was imported in R with the `ape` package function `read.tree()`.

To estimate the absolute cell numbers, the ASVs were corrected for copy numbers of the 16S rRNA gene per cell per specific taxa obtained from the ribosomal RNA database (Stoddard *et al.*, 2015). Total cell numbers per bacterial group and per Liter were then calculated with 16S rRNA gene relative proportions per group and total cell abundance from flow cytometry.

2.8. Data analysis

The difference between total (DNA-based) and potentially active communities (RNA-based) was tested by analysis of similarity (ANOSIM), resulting significant differences ($p=0.001$, $r=0.23$, permutations=999). Likewise free-living and particle-attached fractions for both, total (DNA) and potentially active (RNA) communities revealed significant differences ($p=0.001$, $r=0.57$, for DNA-based set and $p=0.001$, $r=0.41$ for RNA-based dataset, permutations=999).

The analyses performed thereafter considers therefore separately the four subsets, free-living and particle attached fractions for both, total (DNA) and potentially active (RNA) community.

To explore the distribution patterns of the prokaryotic communities we applied Non-Metric Multidimensional Scaling (NMDS), based on the dissimilarity matrix of the community structure. The statistical analyses were performed in R 3.5.3 version (R Core Team, 2019), Bray–Curtis dissimilarity matrices were generated via `vegdist()` function using the relative abundance of ASVs in each sample. Subsequently, the matrix was used to build the NMDS ordinations using `metaMDS()` function in the package *Vegan* (Oksanen *et al.*, 2019).

Diversity indices were calculated with `phyloseq` command `estimate_richness()`. ANOSIM was performed to test significant differences in microbial communities between sampling depths and among sites in the surface mixed layer.

The contribution of individual species (ASVs) to the average Bray-Curtis dissimilarity between the on- and off-plateau groups was obtained using similarity percentage analysis (SIMPER) (Clarke 1993). Station M3 was chosen as the representative off-plateau site and compared to the on-plateau station M2. The analysis was applied to the prokaryotic communities within the wind mixed surface layer. The ASVs with a relative abundance lower than 1% in at least one sample were discarded prior to the SIMPER analysis. Once the ASVs with significant contribution to the dissimilarity between groups were obtained (p-value < 0.005), the ASVs with relative abundance higher than 5% in at least one sample were selected for plotting them in a heatmap using the package pheatmap version 1.0.12 for R (Kolde, 2019).

Partial Mantel tests for the free-living and particle attached fractions in both total (DNA-based) and active (RNA-based) prokaryotic community composition, diatom community composition and environmental parameters (temperature, salinity, concentrations of dissolved oxygen, ammonium, nitrite, nitrate, phosphate, silicic acid and DOC), were performed in Vegan using mantel.partial() based on the Pearson correlation method. Prior to correlation analysis, environmental variables were z-score transformed. The amount of variance in prokaryotic community composition explained by diatoms and environmental parameters was estimated as the square of the correlation coefficient (Rho^2) based on partial Mantel test. The Partial Mantel test was applied to samples in the upper 125m water column, for which diatom community composition was available.

Redundancy analysis (RDA) (Legendre & Legendre, 2012) was applied to evaluate the linkages between the prokaryotic community composition and the environmental parameters in Vegan using rda(). Prior to analysis the environmental variables were z-score transformed

and Hellinger transformation was applied to the community matrix (Legendre & Gallagher, 2001). Permutational multivariate analysis of variance in Vegan with `adonis()` was used to select the significant environmental variables ($p < 0.05$). We used the variance inflation factor (VIF) to determine the linear dependency among variables. We first evaluated all the variables and removed, one at a time, those with a $VIF > 10$ from the dataset. Only the selected variables (with a $VIF < 10$) were used to perform the final RDA analysis. As for the Partial Mantel test, samples in the upper 125m were considered.

3. Results

3.1. Environmental conditions

During late Austral summer the water column was well-stratified, with the wind-mixed surface layer (Z_{ML}) ranging between 49 m and 62 m during the first visits of the off-plateau station M4 (M4-1) and of the on-plateau station M2 (M2-1 and M2-2), respectively (Table 1 and Fig. S2). The occurrence of a storm on March 10th lead to a deepening of the Z_{ML} that was most pronounced at station M4 (87 m). A shallow Z_{ML} (27 m) was determined during our visit at station M1. Temperature in the Z_{ML} was lowest at the southernmost station M4 (4.5°C) and varied between 4.9°C (station M1) and 5.6°C (station M3-1) at the other sites (Table 1, Fig. S2). Seasonally low concentrations of Chl *a* were determined at all sites (Fig. S1), and those in the Z_{ML} of the on plateau station M2 (0.27-0.58 $\mu\text{g L}^{-1}$) were 2-3-fold higher as compared to those at the off-plateau stations M3 (0.14-0.19 $\mu\text{g L}^{-1}$) and M4 (0.18-0.21 $\mu\text{g L}^{-1}$) (Fig. 2), and similar to those at station M1 (0.34 $\mu\text{g L}^{-1}$). (Chl *a*, DOC and prokaryotic abundance for station M1 are illustrated in Fig. S3). Chl *a* concentrations doubled in the Z_{ML} between the 2nd and 3rd visit at the on-plateau site M2.

Concentrations of dissolved organic carbon (DOC) were $54.1 \pm 0.6 \mu\text{M}$ in the Z_{ML} of station
 340 M2 (all visits pooled), as compared to $50.5 \pm 0.7 \mu\text{M}$ at station M3 and $50.3 \pm 0.8 \mu\text{M}$ at station
 M4 (Fig. 2). This accumulation of DOC is likely a consequence of the enhanced seasonal
 phytoplankton activity in Kerguelen plateau waters. Heterotrophic prokaryotic abundance was
 as high as $1.17 \times 10^6 \text{ cells mL}^{-1}$ in the Z_{ML} during our first visit of the on-plateau station M2,
 and cell abundances decreased to $0.81 \times 10^5 \text{ cells mL}^{-1}$ and $0.68 \times 10^5 \text{ cells mL}^{-1}$ during the
 345 following one and two weeks, respectively. Moderate (from 6.96 to $4.45 \times 10^5 \text{ cells mL}^{-1}$ at
 M3) and minor decreases (from 5.52 to $5.01 \times 10^5 \text{ cells mL}^{-1}$ at M4) were observed at the off-
 plateau stations over the 2 weeks that separated the visits (Fig. 2). The prokaryotic cell
 abundance in the $< 0.8 \mu\text{m}$ fraction accounted for $89 \pm 11 \%$ ($n=10$) (Table S1) of the
 abundance in unfiltered seawater in surface waters at the different sites.

3.2. Vertical and spatial structuring of prokaryotic communities

When considering the entire data set, NMDS ordination revealed a clustering by depth layer,
 for the total and active prokaryotic communities in both size fractions. Samples collected for
 the free-living fraction at 10 m and 60 m, corresponding to the Z_{ML} except for station M1
 355 (Table 1), clustered and were distinct from those of 125 m and 300 m (Anosim, $r=0.69$ for
 DNA and $r=0.61$ for RNA, $p=0.001$) (Fig. 3a for DNA and Fig. S4a for RNA). In the case of
 the particle-attached fraction, the clustering by depth was less pronounced, but still significant
 (Anosim, $r=0.58$ for DNA and $r=0.67$ for RNA, $p=0.001$) (Fig. 3b for DNA and Fig. S4b for
 RNA). We determined multiple diversity indices that all revealed an increase with depth in
 360 both size-fractions (Table S2) as illustrated for the Shannon index on Table 2.

To identify possible differences in the prokaryotic community composition among sites, we
 then focused on samples collected in the Z_{ML} . For the free-living fraction, samples grouped

according to station (ANOSIM, $r=0.77$ for DNA and $r=0.51$ for RNA, $p=0.001$)(Fig. 3a and Fig. 4a). This pattern was again less pronounced for the particle-attached fraction (ANOSIM, $r=0.62$, $p=0.001$ for DNA and $r=0.41$ $p=0.006$ for RNA)(Fig. 3b and Fig. S4b). Diversity of the total free-living communities was significantly lower in the Z_{ML} of the on-plateau station M2 (Shannon: 4.34 ± 0.19 for DNA, $n=6$) as compared to that in off plateau waters at stations M1, M3 and M4 (Shannon: 4.86 ± 0.15 for DNA, $n=9$)(one-way ANOVA $p<0.001$). This trend was, however, not observed for the potentially active free-living communities (Shannon: 5.28 ± 0.71 at station M2 and 5.53 ± 0.77 in the off-plateau stations, $n=9$) and the particle-attached communities in the DNA and RNA data sets (Table 2 and Table S2).

3.3. Prokaryotic community composition in surface waters

We further explored in more detail the prokaryotic community composition in surface waters (10 m). The total free-living and particle-attached prokaryotic communities were dominated by *Flavobacteriales* (relative contributions of 53% and 64% in on-plateau waters, 35% and 36% in off-plateau waters, respectively) and *Rhodobacterales* (20% and 10% on-plateau, 17% and 22% off-plateau, respectively). *Cellvibrionales* represented 13% in both size fractions at the on-plateau station (M2), while at the off-plateau stations this order was substantially more abundant in the particle-attached (17%) than in the free-living fraction (3%) (Fig. 4; RNA data are illustrated in Fig. S5). Distinct features of the free-living communities in off-plateau waters were the comparably higher contributions of the SAR11 clade, belonging to *Pelagibacterales* (SAR11, 17-25%), the SAR86 clade (5-8%), *Thiomicrospirales* (2-3%) and *Puniceispirillales* (2-4%). *Verrucomicrobiales* were present only in the total particle-attached communities and their relative abundances were higher in the off-plateau sites (4 - 8%) than in on-plateau waters (1.3%). *Chitinophagales* were detectable only in the particle-attached

fraction at station M2 in both the total (2.2%) and potentially active communities (3.2%), while *Sphingomonadales* (2.5%), *Lactobacillales* (1.4%) and *Rickettsiales* (1.3%) appeared to be specific to the total particle-attached communities at station M1.

390 The high resolution allowed us to identify the relative contribution of the members of the prokaryotic community at the level of ASVs. Interesting information derived at this level of resolution is that in the case of some of the abundant taxonomic groups composed by multiple ASVs, only a few of them were highly abundant. For example, in the total free-living fraction (Fig. S6), *Flavobacteriales* were composed of 24 ASVs, however, only some of them were
395 more abundant in on-plateau than in off-plateau waters. This was the case for ASV6 *Ulvibacter*, ASV12 (NS2b marine group), ASV23 (*Flavobacteriaceae* ASV15 *Aurantivirga* and ASV36 *Polaribacter*). By contrast, other *Flavobacteriales* ASVs were relatively more abundant in off-plateau waters, such as ASV3 *Formosa*, ASV38 and ASV88 (both NS7 marine group). Another interesting observation is that the most abundant ASV from our
400 dataset, ASV1 OM60(NOR5), belonging to the gammaproteobacterial clade, was only highly abundant in the free-living fraction of the on-plateau station M2, which was not the case for the off-plateau free-living community (Fig. S6). By contrast, the same ASV was highly abundant at all sites in the particle-attached total community, and less abundant in the potentially active community (Fig. S7). Given these patterns obtained from our high
405 resolution results of the community composition, we decided to explore which prokaryotes explained the difference among sites.

3.4. Identification of site-specific prokaryotes

To address the question of which prokaryotic taxa explained the difference in the community
410 composition between on- and off-plateau sites (Fig. 3 and Fig. S4), we performed a Simper

analysis (permutations = 999) and selected the ASVs contributing significantly ($p < 0.05$) to the differences between stations at 10 m and 60 m. Because seasonal Chl *a* concentrations were lower at M3 as compared to M4 (Fig. S1) we chose station M3 as a representative off-plateau site for the further comparison with station M2. In order to simplify the visualization of the information, we considered only highly abundant ASVs (relative abundance > 5% in at least one sample).

A total of 9 and 8 highly abundant ASVs, respectively, contributed significantly to the differences in the total (DNA) or potentially active (RNA) free-living communities between stations M2 and M3 at 10 m (Fig. 5; results for 60 m are shown in Fig. S8); among those, 5 ASVs were shared between the DNA and RNA datasets. The 9 and 8 ASVs explained each 24% and 8% of the differences among sites in the total and potentially active free-living communities, respectively. For the particle-attached communities 6 and 3 ASVs contributed significantly to the respective differences and these ASVs explained 28% and 4% of the observed variability. Two ASVs (ASV5 and ASV15) significantly contributed to the differences in both size fractions of the DNA and RNA dataset.

ASVs that had higher relative abundances at station M2 as compared to station M3 belonged to the OM60 group (NOR5 clade, *Haliaceae* ASV1), the *Flavobacteriaceae* NS5 marine group (ASV11), the genera *Aurantivirga* (ASV15) and *Ulvibacter* (ASV6), and ASV5 and ASV23 (not identified on the genus level), the *Saprospiraceae* (ASV33) and the *Cryomorphaceae* NS10 marine group (ASV52). The *Pirellulaceae* genus *Blastopirellula* (ASV8) had low relative abundances in the free-living fraction at station M2 (<0.1%) and this ASV was absent from station M3. ASVs with higher relative abundances at station M3 as compared to station M2 were the *Flavobacteriaceae* genus *Formosa* (ASV3), and the *Rhodobacteraceae* genera *Planktomarina* (ASV16) and *Loktanella* (ASV18). Contrasting patterns were observed for the SAR11 clade (ASV9) that had higher relative abundances in

the total free-living communities at station M3, but a higher contribution to the potentially active free-living communities at station M2.

3.5. Changes in the absolute abundance of major taxa

To explore the question of whether the pronounced decrease in bulk prokaryotic abundance
440 between repeated visits at station M2 (Fig. 2) were due to changes in specific taxa, we
estimated the absolute abundances of ASVs, grouped at the order level, using previously
published rRNA operon copy numbers (Stoddard *et al.*, 2015). Our results reveal an increase
in the abundance of SAR11 from the first to the third visit (by up to 150%) at station M2 at 10
m and a decrease in the abundance of all other considered taxa by on average $48 \pm 12\%$ and
445 $65 \pm 10\%$ after one and two weeks, respectively (Fig. 6; RNA results are shown in Fig. S9).

3.6. Linking prokaryotic community composition to biotic and abiotic factors

The combined set of abiotic environmental parameters and diatom community composition,
as determined by microscopic observations (Lafond *et al.*, 2020), could each explain changes
450 in the total and potentially active prokaryotic communities in both size fractions and all depth
layers ($p < 0.05$; partial Mantel test; Table S3). Environmental parameters could explain 12%
and 16% of the spatio-temporal changes in the total and potentially active free-living
communities, respectively, and 9% and 10% of the respective particle-attached communities.
Diatoms could explain 36% and 28% of the changes in the total and active free-living
455 communities, respectively, and 20% and 14% of the total and active particle-attached
communities. An additional RDA-analysis revealed a clear distinction in on and off-plateau
prokaryotic communities in the Z_{ML} while samples from 125m of all sites grouped (Fig. S10).
Among the environmental parameters tested (Table S4), significant predictors of the

community composition were temperature, salinity, dissolved oxygen, ammonium, nitrite and
460 DOC. In the Z_{ML} , DOC was a significant predictor for the free-living ($p=0.039$) and particle-
attached fraction ($p=0.01$), and this was the case for salinity and the communities at 125m
($p=0.001$ and $p=0.007$, respectively).

4. Discussion

465 We observed distinct prokaryotic communities in surface waters above the central Kerguelen
plateau as compared to those in off-plateau waters during the post-bloom period in late
Austral summer. These findings add to observations from early spring (Landa *et al.*, 2016)
and summer (West *et al.*, 2008; Obernosterer *et al.*, 2011) corresponding to the onset, peak
and early decline of the phytoplankton bloom. A similar spatial structuring was also reported
470 for diatoms (Armand *et al.*, 2008; Lasbleiz *et al.*, 2016; Lafond *et al.*, 2020), non-diatom
phytoplankton and protists (Georges *et al.*, 2014; Irion *et al.*, 2020; Sassenhagen *et al.*, 2020)
during the different bloom phases, and indicates a seasonally persistent influence of natural
Fe fertilization on unicellular plankton communities. We discuss in the following the potential
role of abiotic and biotic factors to better understand this pattern and the role of specific taxa
475 in the microbial cycling of elements.

4.1. Post-bloom conditions and bulk prokaryotic features

A distinct feature of the surface waters above the Kerguelen plateau in late summer is the
accumulation of DOC. Both, the Partial Mantel test and RDA analysis indicated that DOC
concentrations had significant influence on the prokaryotic community composition in the
480 wind mixed surface layer (Table S3, Fig. S10). The higher DOC concentrations likely result
from the seasonally enhanced autotrophic activity, the excretion of phytoplankton-derived
organic matter as cells become less active when entering a senescent stage (Myklestad *et al.*,

1989; Barofsky *et al.*, 2009), and the release of DOC due to grazing (i.e. ‘sloppy-feeding’) (Steinberg and Landry, 2017), leading to a relief of organic carbon limitation (Obernosterer *et al.*, 2015). Besides the quantity, the composition of organic matter could differ among on- and off-plateau sites as a consequence of the varying productivity regimes and thereby contribute to shaping the community composition. The high similarity among prokaryotes at the off-plateau sites, despite their location in different water masses supports this idea.

Seasonal observations in Kerguelen plateau surface waters could provide some insights on organic matter availability and its influence on community composition. Prokaryotic growth rates determined during the post-bloom period (0.04 to 0.15 d⁻¹) (Christaki *et al.*, 2020) were in the same range as those in early spring (0.025 to 0.12 d⁻¹) (Christaki *et al.*, 2014), and lower than those determined in summer (0.22 to 0.47 d⁻¹) (Christaki *et al.* 2008), suggesting an increase in organic matter availability during the peak and early decline of the bloom. The seasonal modifications in organic matter availability were paralleled by changes in prokaryotic diversity. In late summer, the Shannon index in Kerguelen plateau surface waters was in the same range to those determined in early spring at the same site (about 4.5), while a drop to 2.5 was observed following the peak of the spring bloom (Liu *et al.*, 2020). This latter observation points to the dominance of a few fast-growing opportunists taking advantage of the labile organic matter during the peak and just after the bloom (Liu *et al.*, 2020), while the utilization of the post-bloom organic matter pool appears to be attributable to a large number of taxa with well-defined ecological niches.

4.2. Abundant prokaryotic taxa in Kerguelen plateau waters in late summer

Flavobacteriaceae were present at all sites, but accounted for up to 53% and 63% of relative abundance of the free-living and particle-attached total community in Kerguelen plateau surface waters. Members of this family contain a diverse repertoire of enzymatic capabilities for the degradation of complex compounds, including those of phytoplankton origin

(Kappelmann *et al.*, 2019). Substrate preferences vary among taxa (Xing *et al.*, 2015; Krüger *et al.*, 2019) leading to the niche partitioning among diverse members of this family,

510 including the late summer community in Kerguelen plateau waters (Sun *et al.*, in press).

Aurantivirga explained differences between on- and off-plateau waters in the total and potentially active communities in both fractions. *Aurantivirga* was shown to account for about 10% throughout the summer period in Kerguelen plateau waters (Liu *et al.*, 2020). The key role of *Aurantivirga* could be explained by the high number of polysaccharide uptake loci (PULs) and the diverse substrate spectra for glycan degradation reported for members of this 515 genus (Krüger *et al.*, 2019). On the contrary, the *Flavobacteriaceae* genus *Formosa* had higher abundances in off plateau waters, and thus appears to be adapted to a more oligotrophic-type lifestyle.

520 One ASV belonging to the OM60 group (*Gammprotoebacteria*, NOR5 clade, *Halielaceae*) was among the most abundant taxa of our dataset and this ASV contributed significantly to the differences in communities between on- and off plateau surface waters. This contrasts observations from November through February when the relative abundance of this group remained low (< 2%) in plateau waters (Liu *et al.*, 2020). This clade comprises aerobic 525 anoxygenic phototrophs and members associated to aggregates where they thrive under sub-oxic conditions (Fuchs *et al.*, 2007). In the present study, this ASV was highly abundant in the total particle-attached community (DNA-based) at all sites (Fig. S8). Another interesting feature is the potential implication of members of this clade in the degradation of the sulphur compound dimethylsulfoniopropionate (DMSP) (Nowinski *et al.*, 2019; Steiner *et al.*, 2019).

530 Kerguelen surface waters were not enriched in particulate DMSP in summer during the peak of the diatom-dominated bloom (Belviso *et al.*, 2008). However, the shift to non-diatom phytoplankton, including DMSP producers such as Haptophytes (Schoemann *et al.*, 2005),

dominated by *Phaeocystis Antarctica* in the study region (Irion *et al.*, 2020) could suggest a different scenario in late summer. The changes in the late summer light regime due to the low phytoplankton biomass in the well-stratified shallow surface mixed layer and changes in organic carbon sources provided by non-diatom phytoplankton could have led to the success of the OM60 group. One ASV belonging to *Saprospiraceae* (*Chitinophagales*) was highly abundant in the particle-attached community, but accounted for <1% on a seasonal scale (Liu *et al.*, 2020). *Saprospiraceae* were shown to respond in terms of relative abundance in incubation experiments enriched in alginate particles (Mitulla *et al.*, 2016). The associated glycolytic abilities could be advantageous for members of this family in the occupation of a specific substrate niche, provided for example by aggregates of detrital and non-living cells that contributed to up to 65% to total particulate organic carbon in late summer in Kerguelen plateau surface waters (Lafond *et al.*, 2020).

4.3. Potential role of biotic interactions in shaping community composition

Diatom assemblages explained a substantial part of the changes in prokaryotic community composition, despite their lower biomass as compared to other bloom phases (Irion *et al.*, 2020; Lafond *et al.*, 2020). Diatoms were shown to be drivers of the prokaryotic community composition in the Southern Ocean on spatial (Liu *et al.*, 2019) and seasonal scales (Liu *et al.*, 2020), with diatom-derived DOM playing an important role in spring (Landa *et al.*, 2016). In late Austral summer, *Corethron inerme* accounted for 60-80% of total diatom biomass and it was among the most actively silicifying species in on-plateau waters (Lafond *et al.*, 2020). On a seasonal scale, *C. inerme* had a large number of positive correlations with free-living and attached prokaryotes in Kerguelen plateau waters (Liu *et al.*, 2020). These included taxa identified in the present study as being more abundant in on-plateau waters, in particular those belonging to *Flavobacteriaceae* and *Cryomorphaceae*. Another diatom abundant in Austral

summer in the study region is *Rhizosolenia* spp. (Armand *et al.*, 2008; Blain *et al.*, 2020; Lafond *et al.*, 2020). This diatom revealed strong positive correlations with the *Roseobacter* genus *Loktanella* (Liu *et al.*, 2020), a taxon that was highly abundant in off-plateau waters in the particle-attached fraction in the present study. *Corethron* spp. and *Rhizosolenia* spp. are both large diatoms (about 20 μm equivalent spherical radius, ESR), and could thus present habitats for taxa with a particle-attached lifestyle.

The marked decrease in bulk prokaryotic abundances during the consecutive visits at the on-plateau station was predominantly due to grazing by heterotrophic nanoflagellates (Christaki *et al.*, 2020). This raises the question of whether selective ingestion could have influenced prokaryotic community composition. Our observations of a narrow range in the decrease of taxon-specific cells over time suggests grazing to be non-selective, but rather a function of the cell abundance and thus the encounter rate of a given taxon. In addition, prokaryotic community composition did not change substantially between visits at station M2, despite the high grazing activity. While a number of experimental studies carried out with freshwater communities demonstrate the influence of grazers on prokaryotic community composition (see review by Hahn and Höfle, 2001), experimental studies have revealed positive (Teira *et al.*, 2019) or no marked effects (Yokokawa and Nagata, 2005; Landa *et al.*, 2014; Baltar *et al.*, 2016) of the presence of grazers on marine prokaryotic diversity and composition. Our observations appear to be in line with these latter reports and suggest a minor influence of grazers on the temporal changes of the prokaryotic community composition in Kerguelen plateau waters.

4.5. Conclusions

Our observations from late Austral summer add another piece to the pictures obtained during early spring and summer and thereby extend our previous conclusions on the pronounced

effect of natural Fe fertilization on prokaryotic community composition to the post-bloom period. The accumulation of DOC, as a consequence of the high seasonal productivity in Kerguelen plateau waters, together with the potential prokaryote-diatom interactions
585 contribute to the build-up of prokaryote bulk biomass and to their taxonomic composition. The capabilities in the access to different forms of Fe, key for the processing of organic matter, vary among prokaryotic groups (Debeljak *et al.*, 2019) and likely play an additional role in shaping microbial communities. Our results suggest that the most abundant prokaryotic taxa identified as specific to the productive Kerguelen plateau surface waters in
590 late summer contribute to the transfer of organic matter to heterotrophic nanoflagellates (Christaki *et al.*, 2020) and potentially higher trophic levels.

Figure Legends

Figure 1. Map of the MOBYDICK station locations. Surface chlorophyll concentrations are from Global Ocean Satellite Observations (Copernicus-GlobColour). Reprocessed data are provided by Copernicus Marine Service. Chlorophyll concentrations are the monthly mean for March 2018 at a resolution of 4 km. The black lines denote 1000 m bathymetry.

Figure 2. Vertical profiles of Chl *a*, DOC and prokaryotic abundance at the on-plateau station M2 and the off-plateau stations M3 and M4. Chl*a* and prokaryotic abundances are shown for each visit, DOC concentration is given as the mean of the repeated visits. Data for station M1 are shown in Fig. S3.

Figure 3. Non-Metric Multidimensional Scaling (NMDS) of total (DNA) prokaryotic communities in the (a) free-living and (b) particle-attached fraction from all depth layers based on Bray-Curtis Dissimilarity. Sample depths are indicated by color, sampling sites by symbol and the number of visit is indicated with a number next to the respective symbol (see Table 1 for more information about sampling scheme.)

Figure 4. Relative abundance of total (DNA) free-living (FL) and particle-attached (PA) taxa grouped at order level in surface waters (10 m). For stations M2, M3 and M4 the relative abundances of the first visit are shown.

Figure 5. Relative abundance of ASVs that contribute significantly ($p < 0.05$) to the dissimilarity between stations M2 and M3 (SIMPER analysis) at 10m. Asterisk highlight significant differences for a given ASV between sites, in either the free-living or particle-attached fractions, for the total (DNA) or potentially active (RNA) communities. Only the ASVs with relative abundance $> 5\%$ in at least one of the samples are shown. Note that the

ASVs that contribute to the difference among sites are not always the same for the total and
815 the active communities

Figure 6. Changes in the absolute abundance of dominant taxa (DNA, free-living fraction) between the first and the second (M2_3) and the first and the third (M2_3) visit at station M2 at 10 m. Deviations are given as percent; positive and negative values indicate an increase and a decrease, respectively, in abundance over the repeated visits at station M2. The deviation
820 was calculated based on a formula published in Agogu *et al.* (2011).

Sequencing data. Demultiplexed sequence files are available in NCBI under accession number PRJNA679029.

Acknowledgments

We thank B. Quguiner, the PI of the MOBYDICK project, for providing us the opportunity
825 to participate to this cruise, and the captain and crew of the *R/V* Marion Dufresne for their enthusiasm and support aboard during the MOBYDICK– THEMISTO cruise (<https://doi.org/10.17600/18000403>). This work was supported by the French oceanographic fleet (“Flotte ocanographique franaise”), the French ANR (“Agence Nationale de la Recherche”, AAPG 2017 program, MOBYDICK Project number : ANR-17-CE01-0013), and
830 the French Research program of INSU-CNRS LEFE/CYBER (“Les enveloppes fluides et l’environnement” – “Cycles biogochimiques, environnement et ressources”). We thank P. Catala for flow cytometry analyses. We are grateful to A. Lafond and J. Legras for sharing with us the diatom species abundances obtained by microscopic observations. We thank the GenoToul Bioinformatics platform (<http://bioinfo.genotoul.fr/>) for providing computing
835 resources. Y.L. was supported by the China Scholarship Council (CSC; No. 201606330072). Three reviewers provided constructive comments that helped improve a previous version of the manuscript.

Supplementary Figures

Figure S1. Seasonal bloom dynamics for on-plateau station M2 and off-plateau stations M3 and M4. The green line indicates the 10-year climatological mean (2007-2017) of Chl *a* concentrations and its SD illustrated as the green shaded area. The blue line denotes Chl *a* concentrations for the year 2018 (MOBYDICK cruise). Chl *a* data are from Global Ocean Satellite Observations (Copernicus-GlobColour). Reprocessed data are provided by Copernicus Marine Service. The time period of the MOBYDICK cruise is marked with a rectangle. Note different scales of y-axis.

Figure S2. Depth profiles of temperature and density anomaly for the repeated visits at the 4 stations.

Figure S3. Depth profiles of DOC, prokaryotic abundances and Chl *a* at station M1.

Figure S4. Non-Metric Multidimensional Scaling (NMDS) of potentially active (RNA) prokaryotic communities in the (a) free-living and (b) particle-attached fraction from all depth layers based on Bray-Curtis Dissimilarity.

Figure S5. Relative abundance of potentially active (RNA) free-living (FL) and particle-attached (PA) taxa grouped at order level in surface waters (10 m). For stations M2, M3 and M4 the mean relative abundances of the repeated visits are shown.

Fig. S6. Relative abundance of ASVs with corresponding phylum (right colored sidebar) in the free-living fraction in surface waters (10 m). Only ASVs with >1% relative abundance in at least one sample are shown. On-plateau in green; off-plateau in blue. DNA: total community, RNA: potentially active community.

Fig. S7. Relative abundance of ASVs with corresponding phylum (right colored sidebar) in the particle-attached fraction in surface waters (10 m). Only ASVs with >1% relative abundance in at least one sample are shown. On-plateau in green; off-plateau in blue. DNA: total community, RNA: potentially active community.

Fig. S8. Relative abundance of ASVs that contribute significantly ($p < 0.05$) to the dissimilarity between stations M2 and M3 (SIMPER analysis) at 60m. Asterisk highlight significant differences for a given ASV between sites, in either the free-living or particle-attached fractions, for the total (DNA) or potentially active (RNA) communities. Only the ASVs with relative abundance >5% in at least one of the samples are shown. Note that the ASVs that contribute to the difference among sites are not always the same for the total and the active communities

Fig. S9. Changes in the absolute abundance of dominant taxa (RNA, free-living fraction) between the first and the second (M2_3) and the first and the third (M2_3) visit at station M2 at 10 m. Deviations are given as percent; positive and negative values indicate an increase and a decrease, respectively, in abundance over the repeated visits at station M2. The deviation was calculated based on a formula published in Agogu et al (2011).

Fig. S10. Redundancy analysis of the total community (DNA-based dataset) in the free-living fraction (a) and particle attached (b). The significant environmental response-vectors are shown. Colors indicate water depths and symbol shapes correspond to sites. The variables were selected prior the RDA analysis (with variance inflation <10) excluding the redundant constraints.

Table S1. Percent prokaryotic cells in the 0.8 μm filtered seawater of cells in unfiltered seawater.

Station	Depth (m)	Fraction of cells in < 0.8 μm size fraction (%)
M1	15	115

Table S3. Partial Mantel tests for total (DNA) and potentially active (RNA) prokaryotic community composition, diatom community composition and environmental parameters. Rho values are shown. ** $p < 0.01$, * $p < 0.05$. Diatom community composition was determined by microscopic observations and the results are presented in Lafond et al. (2020)
