Keywords: sickle cell disease, endothelium, hemolysis, microparticles, heme, proteasome.

Sickle cell disease (SCD) results from a unique mutation in the β -globin gene and is the most common genetic hemoglobinopathy. It is characterized by hemolytic anemia, painful vaso-occlusive crisis and progressive organ failure including nephropathy. Red blood cells (RBCs) in patients with SCD are subjected to constant endogenous and exogenous oxidative stress, which in turn increase hemolysis and contribute to vasculopathies. A gradient of hemolysis among SCD patients influences the SCD phenotype ¹. Included in the vasculopathic subphenotypes associated with hyperhemolysis are pulmonary hypertension, cerebrovascular disease, leg ulcers, priapism, and sickle cell nephropathy. To what extent and how chronic hemolysis and hemoglobinuria contribute to sub-phenotypes in SCD remains unclear. A recent study by S. Jana et al. sheds light on the pathophysiological role of intracellular hemoglobin S (HbS) oxidation in RBC and RBC-derived microparticles, suggesting potential antioxidative therapies for SCD vasculopathy and nephropathy ².

Oxidized hemoglobin is toxic to endothelial cells. Outside of the protective environment of RBCs, hemoglobin is prone to oxidation, leading to the formation of oxidized hemoglobin forms. Methemoglobin (metHb) results from oxidation of the iron moieties in hemoglobin from the ferrous (Fe²⁺) to the ferric (Fe³⁺) state. Ferryl hemoglobin (ferryl Hb, HbFe⁴⁺)

results from further oxidation and is highly reactive. When oxidation of hemoglobin facilitates release of its heme groups, catalytically active iron is provided to neighboring cells. Although hemoglobin is relatively innocuous to cultured endothelial cells, when oxidized to metHb it amplifies oxidant-mediated endothelial cell injury.⁴ Ferryl Hb also has proinflammatory effects on endothelial cells, an effect that is not observed with hemoglobin or metHb³.

During hemolysis, RBCs release a large number of fragments, known as microparticles. These microparticles also contain hemoglobin, but in a degraded and toxic form: the iron previously contained in the hemoglobin becomes exposed on the surface of RBC microparticles. *In vitro*, heme-laden RBC-derived microparticles from patients with SCD or from sickle cell mice transfer heme to cultured endothelial cells, inducing oxidative stress and apoptosis. In a mouse model of SCD that develops vaso-occlusive crisis and sickle cell nephropathy, infusion of heme-laden microparticles acutely triggered renal vaso-occlusive crisis ⁴. The vascular effects triggered by RBC-derived microparticles were largely blocked by a heme-scavenger ⁴.

The vaso-occlusive action of heme-laden RBC-derived microparticles, and the endothelio-toxic effect of oxidized hemoglobin forms raised the question of whether intracellular oxidation of hemoglobin takes place in the oxidative environment of SCD RBCs and microparticles and whether HbS would be more prone to such oxidation than HbA.

To address this question, the Alayash laboratory monitored the kinetics of hemoglobin oxidation in RBC-derived microparticles generated from humanized mice with knock-in of normal adult hemoglobin (HbA) or sickle HbS. The authors focused on the intrinsic pseudoperoxidase activity of hemoglobin, which determines RBC cytosolic and membrane alterations ². Very little spontaneous auto-oxidation of free HbA was observed compared to the oxidation of HbS, suggesting a pro-oxidative milieu in the sickle cell microparticles. Ferryl Hb was detectable only in microparticles prepared from the humanized HbS mice.

When challenged with hydrogen peroxide, HbS is known to undergo oxidative changes affecting the structure of both the alpha and beta subunits. In the current model, challenge

with hydrogen peroxide resulted in a marked reduction of free HbS subunits over a 36-hour incubation period, with no significant effect on HbA subunits. The observed effects were blunted in HbS mice treated with hydroxyurea, which prevents vaso-occlusive crisis and some of the chronic microvascular complications in patients with SCD. The authors also demonstrated that HbS, especially oxidized forms, cause more damage to the endothelial monolayer than HbA. The authors concluded that circulation of microparticles and RBCs containing highly reactive ferryl Hb and heme may promote vasculopathy in SCD.

The study team also demonstrated post-translational modifications of HbS in RBC-derived microparticles. In addition to irreversible oxidation of β Cys93, an established feature of HbS instability, they also observed ubiquitination of two residues of the beta globin chain. The authors hypothesized that the ubiquitination reflects proteasomal inhibition as a result of redox imbalance in sickle RBCs, although alternative hypotheses such as increased activity of the ubiquitination machinery were not fully excluded. In addition, since these observations were made following inhibition of the proteasome and deubiquitinating enzymes, the pathophysiological relevance of HbS ubiquitination should be addressed. Remarkably, 10 days of hydroxyurea treatment in sickle cell mice was sufficient to reverse the post-translational alterations of HbS in RBC-derived microparticles, suggesting an antioxidant effect of hydroxyurea. Interestingly, chronic hydroxyurea administration is associated with a decline of albuminuria in patients with SCD.⁵

These findings are reminiscent of an earlier report suggesting that in addition to redox reactivity, heme may adversely alter cellular functions by binding to essential proteins and impairing their function. Demonstration of heme binding to the proteasome was actually previously linked to impaired proteasome function in *Hmox1*-deficient mouse embryo fibroblast cells⁶. Taken together, a novel model of cellular heme toxicity could be proposed, whereby proteasome inhibition by heme sustains a cycle of oxidative stress, protein modification, accumulation of damaged proteins, and cell death. Because the alterations of HbS were found following inhibition of the proteasome and deubiquitinating enzymes, the pathophysiological significance of ubiquitination of HbS should be addressed.

The authors have nicely demonstrated that purified ferryl Hb can effectively promote complexes with RBC band 3 proteins, consistent with a recent study ⁷. Oxidation of HbS generates products with high affinity toward the cytoplasmic domain of band 3 and is reported to mediate oxidative crosslinking ⁸. Band 3 clustering causes RBC membrane alterations that may promote microparticle generation, and may be involved in kidney vaso-occlusion ⁹. We previously found that microparticles derived from sickle cell RBCs but not from normal RBCs triggered renal vaso-occlusive crisis in mice. We also observed hemoglobin accumulation within tubulo-interstitial and glomerular capillaries in kidney biopsies from patients with SCD, suggesting a pathological role in the progression of sickle cell nephropathy ⁹. We hypothesize that transfer of cytotoxic microparticles to the glomerular endothelium may also contribute to severe endothelial dysfunction or exposure of the subendothelial matrix in a subset of patients who suffer from severe SCD nephropathy with features of glomerular thrombotic microangiopathy. By demonstrating that HbS, especially the oxidized forms, can cause more damage to endothelial monolayer than HbA, the study by Jana et al. adds further mechanistic evidence that such action involves microparticle-borne ferryl HbS with post-translational modifications.

Overall, this novel work suggests a potential role for intracellular HbS oxidation in RBCs and RBC-derived microparticles in promoting the vascular complications of SCD. Anti-oxidant interventions may limit hemoglobin oxidation in SCD RBCs and RBC-derived microparticles, offering a potential therapeutic approach to prevent or mitigate SCD vasculopathy and hopefully sickle cell nephropathy.
