Abstract

Tellurium (Te) is a Technology Critical Element (TCE) and a relevant product of nuclear fission. It has an unknown environmental biogeochemical cycle, mostly related to current analytical challenges in measuring its ultra-trace dissolved concentrations in complex environmental matrices. It is therefore generally compared to its geochemical pair selenium (Se), which shows a narrow range between diet essentiality and toxicity properties. Batch experiments using isotopically-labelled stable Te and Se were performed with fresh suspended particulate matter (SPM) from the fluvial part of the Gironde Estuary, simulating both estuarine salinity ($S=0$ vs $S=32$) and turbidity (100 mg L^{-1} vs 1000 mg L^{-1}) gradients to understand the importance of the particulate phases in Te reactivity under estuarine conditions and verify the resemblance to Se behaviour. These experiments addressed sorption kinetics, sorption isotherms and fractionation from selective extractions of final equilibrated SPM. Results showed a strong, salinity-independent affinity of Te for the particulate phases ($\log_{10} K_d \sim 4.9 \text{ L kg}^{-1}$), following a Langmuir-type isotherm. Contrastingly, Se adsorbs clearly less to estuarine SPM ($\log_{10} K_d \sim 2.5 \text{ L kg}^{-1}$), following a Freundlich-type isotherm. Both isotherms and selective extractions highlighted differences between Te and Se sequestration. Selective extractions suggested higher mobility of particulate Se in contrast to Te. Based on these results the paper sets a first dispersion scenario on the environmental fate of radioactive Te and Se after hypothetical nuclear power plant accidental releases in coastal aquatic systems such as the Garonne-Gironde fluvial-estuarine system.

Keywords: technology critical elements, isotherms, selective extractions, distribution coefficient (K_d), Te environmental cycle, radionuclide releases

1. Introduction

Radioactive tellurium (Te) is produced during nuclear fission reactions in non-negligible quantities. All Te radionuclides have a 13-16% probability of being produced from ^{239}Pu - and ^{235}U -based fuels compared to ~11% for Cs and ~10% for I radionuclides (unpublished data calculated from Element Collection Inc. and Sonzogni 2013). There is little information on the specific Te species released from nuclear power plant (NPP) accidents, potentially presenting both (i) volatile/intermediate (Morewitz 1981), and (ii) refractory character (e.g., forming metal/oxide compounds; Kleykamp 1985; Izrael 2002 and references therein). Though different NPP accidents display different emission patterns, Te radionuclides were released into the environment during both April-1986 Chernobyl (CNPP) and March-2011 Fukushima Daiichi (FDNPP) accidental events (Steinhauser et al. 2014). In these cases, short-term half-life Te radionuclides (e.g., ^{132}Te half-life of 3.2 days) produced important atmospheric radioactive emissions (^{132}Te : ~1150 PBq at CNPP and ~180 PBq at FDNPP) comparable to ^{137}Cs and ^{131}I , the most monitored radionuclides after NPP accidental events (~85 PBq and ~1700 PBq at CNPP, ~37 PBq and ~160 PBq at FDNPP, respectively; Steinhauser et al. 2014). Emitted Te radionuclides were still detected in the atmosphere one month after the FDNPP accident reflecting their non-negligible environmental persistence and potential worldwide atmospheric dispersion (Baeza et al. 2012; Ishikawa et al. 2014; Leppänen et al. 2013). In fact, radioactive Te has been detected in FDNPP fallouts (Saegusa et al. 2013) and in seawater from Monaco, after CNPP (May 1986), yet with relatively low ^{129}Te activities in the dissolved (0.13 Bq L^{-1}) and particulate (1.18 mBq L^{-1}) phases (Whitehead et al. 1988). The latter study further suggested for the first time the moderate particle-reactive behaviour of radioactive Te and its potential intake by marine bivalves, thus, risk of entering environmental food chains (i.e., up to $340 \text{ Bq kg}^{-1} \text{ DW}$ in mussel soft tissues; Whitehead et al. 1988).

On the other hand, radioactive selenium (Se) is a widely known fission product of nuclear reactions. It can be released into the environment during several steps of the nuclear fuel cycle comprising NPP wastewaters and spent nuclear fuel, with recent research focusing specifically on ^{79}Se mobility (half-life of $\sim 10^5 \text{ y}$) from waste storage and nuclear waste disposal areas (Aguerre and Frechou 2006; Asai et al. 2011; Hamed et al. 2017). Selenium is considered a highly soluble, mobile, biologically essential and toxic trace element with a more comprehensive biogeochemical cycle (e.g., Tan et al. 2016; Winkel 2016) than that of Te. Due to their overall chemical similarity (both chalcogens/Group 16 elements), the environmental behaviour of Te is generally assumed to be similar to that of Se (Belzile and Chen 2015).

Given the massive dispersion of past NPP accidental releases through both aquatic and atmospheric compartments, the development of management plans for hypothetical future accidental NPP events requires knowledge on radionuclide behaviour including adsorption kinetics under environmentally-representative conditions. Worldwide, many NPPs are located on fluvial-estuarine systems, for which little is known on Te (Wu et al. 2014; Duan et al. 2014; Biver et al. 2015) and Se (Measures and

Burton 1978; Cutter 1989; Bizsel et al. 2017) environmental dispersion and biogeochemical behaviour.

This study aimed at determining Te and Se reactivity in estuarine salinity and turbidity gradients through isotopically-labelled sorption experiments (kinetics and isotherms) using natural bulk sediments and natural water matrices. Parallel selective extractions of particles previously exposed to isotopically-labelled Te and Se address solid fractionation for both, inherited and spiked concentrations. The results were further compared to dynamic environmental conditions (i.e., environmental timescales of semi-diurnal tidal variations, seasonal migration of the estuarine maximum turbidity zone, etc.). This comparison allowed to assess and predict for the first time the environmental fate and potential dispersion of short-lived Te vs long-lived Se radionuclides in case of a hypothetical accidental NPP liquid discharge in the fluvial-estuarine system of the Gironde Estuary (SW France hosting two NPPs: the Blayais NPP and the Golfech NPP, Gil-Díaz et al. 2018).

2. Material and Methods

2.1. Experimental design

Sorption experiments simulated four experimental conditions representative of the Gironde Estuary salinity and turbidity gradients: two contrasting water matrices (salinities 0 and 32) and two solid/liquid ratios (100 mg L⁻¹ and 1000 mg L⁻¹ DW). Freshwater from the Garonne River and seawater from the Arcachon Bay, were filtered with 0.45 µm Teflon filters (FHLC, Merck Millipore Ltd.). Freshwater sediments were sampled at Portets (~30 km upstream from Bordeaux) on the Garonne River. The water content was evaluated by comparing the masses of precise volumes of wet and dry sediment aliquots.

Spike solutions were prepared by dissolution of elemental ¹²⁵Te (99.89% purity; Cortecnet, France) and ⁷⁷Se (99.20% purity; Cortecnet, France) in HCl (2% Suprapur®, Merck) and HNO₃ (2% Suprapur®, Merck), respectively, heated at 70°C until dissolution. This method is known to produce oxidized species, i.e., well-known reaction for the formation of Se(VI) (Van Dael et al. 2004). Isotopically-labelled Te and Se solutions were further oxidised with H₂O₂ (30 µL L⁻¹ 30% J.T. Baker ultrapure) in the different water matrices to favour the oxidation state of ¹²⁵Te(VI) and ⁷⁷Se(VI) (e.g., Edwards et al. 1959; Horner and Leonard 1952), followed by an equilibration period of 24h. Slurries were prepared from the fresh sediments and unspiked water matrices and equilibrated during 24h, to avoid potential effects of sediment-water interactions during the sorption experiment (e.g., other ionic exchanges related to matrix properties influencing spiked Te or Se adsorption).

Sorption kinetics were performed with nominal concentrations of 5 µg L⁻¹ of ¹²⁵Te(VI) and 100 µg L⁻¹ of ⁷⁷Se(VI). These spike concentrations are higher than those expected in most natural systems but

were required for analytical purposes. All sorption experiments were performed in acid-washed 50 mL centrifuging polypropylene (PP) tubes with 3 replicates per experimental condition. Sorption experiments were placed on an automatic overhead shaker (REAX 20 Heidolph Instruments) and sampled at $t = 0, 2, 4, 8, 24$ and 48h ($N=3$). These relatively short-term experimental conditions are considered to be in accordance with the environmental timescales of highly dynamic environments such as those occurring in continent-ocean transition systems. Temperature ($21.1 \pm 0.4\text{ }^{\circ}\text{C}$), pH (7.50 ± 0.45) and oxic ($104 \pm 0.5\%$ saturation) conditions, were monitored and remained stable throughout the experiment. In parallel, blank tubes containing only spiked water solutions were used to control ^{125}Te and ^{77}Se potential losses onto PP walls over time.

Adsorption isotherms were performed for two SPM concentrations (100 mg L^{-1} and 1000 mg L^{-1}) with initial concentrations of dissolved ^{125}Te of $0.1, 0.25, 0.5, 1, 2.5, 5\text{ }\mu\text{g L}^{-1}$ and initial concentrations of dissolved ^{77}Se of $0.5, 5, 10, 25, 50, 75, 100\text{ }\mu\text{g L}^{-1}$ ($N=2$) and sampled after 48h . Due to analytical constraints (i.e., salt tolerance of the ICP-MS), especially at the low concentration ranges, these experiments were only performed in freshwater conditions.

In both kinetics and isotherm experiments, dissolved Te (Te_d) and dissolved Se (Se_d) were monitored. Particulate concentrations were only determined for isotherm experiments using freshwater slurries with 1000 mg L^{-1} SPM for mass balance calculations. In all cases, the dissolved phase was separated from the particulate phase by centrifugation (10 min at 4000 rpm ; Hettich Rotofix 32A centrifuge) and filtered ($0.2\text{ }\mu\text{m}$ Minisart® cellulose acetate) into acid-washed PP 15 mL tubes. These were then acidified with HNO_3 ($1/1000\text{ v/v}$; J.T. Baker ultrapure, 14 M) and stored at 4°C in the dark until analysis.

2.2. Parallel selective extractions and total digestions

High SPM concentrations ($2 - 4\text{ g L}^{-1}\text{ DW}$) in freshwater ($S = 0$) and seawater ($S = 32$) were left to equilibrate for 48h in spiked solutions of nominal $10\text{ }\mu\text{g L}^{-1}$ of ^{125}Te and $100\text{ }\mu\text{g L}^{-1}$ of ^{77}Se . All sediments were recovered by centrifugation (Hettich ROTOFIX 32A), oven dried (70°C , constant weight) and grinded in agate mortars, then aliquoted and extracted with parallel selective extractions (two replicates per extraction mode, Table 1). The targeted operationally defined solid fractions were: F1 – easily exchangeable and/or carbonate fraction (acetate solution extracting carbonates, Mn oxyhydroxides, sulphates and organic matter phases; Bordas and Bourg 1998; Kersten and Förstner 1987), F2 – reducible Fe/Mn oxides (ascorbate solution extracting Mn oxide and amorphous Fe oxide phases; Kostka and Luther 1994), F3 – oxidisable fraction (H_2O_2 extraction of organic matter and labile/amorphous sulphide phases; Tessier et al. 1979; Ma et Uren 1995) and F4 – reactive and “potentially bioaccessible” fraction ($\text{HCl } 1\text{M}$ acid extraction of amorphous and crystalline Fe and Mn oxides, carbonates, amorphous monosulphurs and phyllosilicate phases; Huerta-Díaz and Morse 1990;

Gasparon and Matschullat 2006). In addition to the latter, acid extraction with HNO₃ 1 M (F4N) was performed on a separate aliquot to discard the Cl effect or specific acid effect on F4 obtained from HCl 1 M leaching. All reagents used were of high purity grade except H₂O₂ (p.a. grade). High Te contamination of ~35 µg L⁻¹ was observed in the extraction blanks of F3 potentially from the H₂O₂ solution or the added ammonium acetate. This contamination is suspected to have been adsorbed into other than H₂O₂-extracted solid fractions (given the Te behaviour, see results), thus not affecting the inherited Te identified in F3 fraction. All extractions were performed in acid-washed (HNO₃ 10%) PP Falcon 50 mL conical centrifuge tubes (Fisher Scientific). Three blanks of each extraction were performed. Currently, no Certified Reference Materials (CRM) are available for Te and Se selective fractions. Residual fractions were calculated as the difference between the acid-soluble fraction (F4 or F4N) and the total adsorbed particulate concentration.

Total sediment concentrations were determined differently for particulate Te (Te_p) and particulate Se (Se_p). Mineralisation of sediment for Te analysis was achieved using a tri-acid digestion with HNO₃ + HCl + HF as described elsewhere (e.g., Schäfer et al. 2002). Briefly, samples of 30 mg were digested in closed PP tubes (DigiTUBE[®], SCP Science) on a heating block (2 h at 110 °C) using 750 µL HNO₃ (14 M Suprapur[®], Merck), 1.5 mL HCl (10 M Suprapur[®], Merck) and 2.5 mL HF (29 M Suprapur[®], Fisher). After an evaporation step at 120°C, re-dissolution of the samples was performed with 250 µL HNO₃ (14 M) and heating. After cooling, the samples were brought to 10 mL using Milli-Q water (18.2 MΩ).

For the analysis of Se_p (volatile at >70°C, not compatible with the above-described tri-acid digestion) total microwave-assisted digestions (START 1500, MLS GmbH) were performed with 40 - 50 mg of sediment aliquots (Eiche et al. unpublished) already dried (50°C drying oven) and homogenised (agate mortar). Briefly, 3 mL HNO₃ (sub-boiled acid-distilled 65%, p.a. grade, VWR Chemicals), 0.5 mL H₂O₂ (30% Rotipuran[®], Carl Roth), 0.25 mL HF (40% Suprapur[®], Merck KGAA Darmstadt) and 0.5 mL ultrapure Milli-Q water were added. The temperature program was: 18°C min⁻¹ to 75°C, followed by 7°C min⁻¹ to 110°C, then 8°C min⁻¹ to 150°C and 6°C min⁻¹ to 210°C, with a constant temperature of 210°C during 10 min before completely cooling down over night. After digestion, samples were transferred into PTFE vessels and evaporated on a hotplate to dryness at 70°C (no Se evaporation at this temperature), recovered with 270 µL of HNO₃ (65% Suprapur), heated at 70°C for 1h and made up with ultrapure Milli-Q water to a final volume of 6 mL.

2.3. Tellurium quantification

Dissolved Te in samples from freshwater kinetics and isotherms experiments were directly analysed by ICP-MS (X-Series II, Thermo Fisher Scientific) using external calibration. Seawater matrices were diluted in 2% HNO₃ (J.T. Baker ultrapure, 14 M) and quantified with external

calibration in an adapted salty matrix. In all cases, recoveries were between 85 – 91% for NIST 1643f CRM (N=4) with a detection limit (LOD) of 0.01 µg L⁻¹ (N=10). Given this LOD, the spiked concentrations and the dilution effect, it is assumed that pre-existing inherited ¹²⁵Te in the kinetics and isotherm samples is negligible in the water matrices as expected concentrations are in the range of 1 ng L⁻¹ (Filella 2013; Belzile and Chen 2015). The latter is corroborated by upstream freshwater analyses (Gil-Díaz et al. 2019a).

Digestates of particles from the isotherm experiments using 1000 mg L⁻¹ SPM in freshwater were quantified with an QQQ-ICP-MS (Agilent 8800, Basel, Switzerland) using an external calibration with ¹⁰³Rh as internal standard to correct for matrix effects. Tellurium was measured in oxygen-shift mode using O₂ as collision gas (¹²⁵Te + ¹⁶O → ¹⁴¹TeO). A certified reference material (NCS 73307) was used for quality check-up of the total digestions showing mean ± SD recovery values of 94 ± 17% (N=3).

Particulate Te in total digestions and selective extractions were quantified by TripleQuad-ICP-MS (TQ ICP-MS; iCAP-TQ, Thermo®) using external calibration. Given the very low inherited Te_p concentrations (~0.04 mg kg⁻¹), natural/inherited Te (Te_{nat}) was quantified from ¹²⁶Te measured in KED-mode (He), correcting for ⁸⁶Sr⁴⁰Ar, ¹¹⁰Cd¹⁶O and ¹¹⁰Pd¹⁶O interferences (Filella and Rodushkin 2018) with respective monoelemental solutions (influencing <0.1%) and ¹²⁶Xe from analytical blanks (2% HNO₃). Spiked/experimental ¹²⁵Te (Te_{ex}) was determined by TQ ICP-MS in mass-shift O₂-mode (iCAP-TQ, Thermo®). Certified reference materials were used for instrumental quality check-up (freshwater NIST 1643f) and total digestions (stream sediment NCS 73307). Recoveries were 95 ± 5% (N=5) in the KED-mode, 89 ± 10% (N=5) in the O₂-mode for NIST 1643f and 99 ± 14% (N=4) in the KED-mode and 70 ± 19% (N=4) in the O₂-mode for NCS 73307. Inherited Te was quantified from both Te-spiked SPM and Se-spiked SPM (i.e., no influence from potential ¹²⁵Te spike effect). In selective extractions, Te_{nat} concentrations ranged from 5-fold (in F2 extractions) to 200-fold (in F4 extractions) above LOD (0.1 ng L⁻¹, N=10).

2.4. Selenium quantification

Dissolved Se concentrations from sorption kinetics and isotherms were quantified by ICP-MS (XSeries 2, Thermo Fisher Scientific, KIT, Germany) using external calibration, CCT-mode (collision cell with He:H₂ mixture at 92%: 8% to minimise ⁴⁰Ar³⁷Cl interferences) and ¹⁰³Rh/¹¹⁵In as internal standards. Analytical quality control was followed with certified drinking water (CRM-TMDW) and freshwater (NIST 1643f) standards showing recoveries ranging between 98 – 106% for the former (N=16) and 100-102% for the latter (N=16), with a LOD of 0.06 µg L⁻¹ (N=10). Natural Se_d concentrations were 0.14 ± 0.03 µg L⁻¹ in freshwater (N=32) and ~0.31 µg L⁻¹ for seawater (unpublished).

Total ^{77}Se digestions from the 1000 mg L⁻¹ SPM isotherm experiment were quantified by QQQ-ICP-MS (Agilent 8800, Basel, Switzerland) using external calibration with ^{103}Rh as internal standard and oxygen-shift mode collision gas for ^{77}Se ($^{77}\text{Se} + ^{16}\text{O} \rightarrow ^{93}\text{SeO}$) to avoid, amongst others, doubly charged Rare Earth Element (REE) interferences (mainly $^{154}\text{Sm}^{++}$, $^{154}\text{Gd}^{++}$). The CRM NCS 73307 showed recoveries of total digestions ranging from 70 to 134% (N=3).

Analyses of Se in selective extractions, namely particulate inherited/natural Se (Se_{nat}) and spiked/experimental Se (Se_{ex}) were quantified with the O₂-mode of the TQ ICP-MS (iCAP-TQ, Thermo®) using external calibration, eliminating the known polyatomic interferences (e.g., $^{40}\text{Ar}^{37}\text{Cl}$, $^{154}\text{Sm}^{++}$ and $^{154}\text{Gd}^{++}$ in ^{77}Se , ^{78}Kr , $^{156}\text{Gd}^{++}$ and $^{156}\text{Dy}^{++}$ in ^{78}Se , $^{81}\text{Br}^1\text{H}$ and ^{82}Kr in ^{82}Se) on both inherited (^{78}Se , ^{80}Se , ^{82}Se) and spiked (^{77}Se) isotopes. Particulate Se_{nat} was quantified from both Te-spiked and Se-spiked slurries. Analytical quality check showed recoveries of $95 \pm 3\%$ for NIST 1643f and $85 \pm 2\%$ for NIST 1640a. Total adsorbed Se_{ex} was calculated from the difference between initially spiked and final Se_{d} after 48h.

2.5. Distribution coefficient (K_d)

Tellurium and Se partitioning between dissolved and particulate concentrations was evaluated from the kinetic experiments at equilibrium by using the particle-water distribution coefficient (K_d), described in Sung (1995). Briefly, K_d (in L kg⁻¹) is the particulate (mg kg⁻¹) to dissolved (mg L⁻¹) concentration ratio (Equation 1). The relative contribution of the particulate concentration (X_p) of a given element X to the total (dissolved + particulate) concentration of the same element (X_T, Equation 2) is expressed as the fraction of X_p (F_p, expressed in percentage, Equation 3).

$$K_d = X_p/X_d \quad (1)$$

$$X_T = X_p \cdot \text{SPM} + X_d \quad (2)$$

$$F_p(\%) = (X_p \cdot \text{SPM})/X_T = (K_d \cdot \text{SPM})/(1 + K_d \cdot \text{SPM}) \quad (3)$$

where X_p is expressed in mg kg⁻¹, X_d in mg L⁻¹, X_T in mg L⁻¹ and SPM in kg L⁻¹. This K_d should also match the slope of the isotherm experiments.

2.6. Adsorption isotherm models

The exchange of a substance between the dissolved and particulate phases reaches a dynamic equilibrium (i.e., equal sorption and desorption rates) after sufficient contact time (Foo and Hameed 2010). Appropriate modelling and thermodynamic considerations provide insights into the adsorption

mechanisms (i.e., physisorption vs chemisorption), surface properties and sorption strength (Foo and Hameed 2010, and references therein).

The Langmuir empirical model is the most common two-parameter isotherm employed to describe monolayer chemical saturation onto finite sites with no lateral interactions between adsorbed molecules (no “steric hindrance”; Langmuir 1918). The mathematical equation for the Langmuir isotherm (Equation 4) is complemented with the dimensionless constant (R_L) also known as the separation factor or equilibrium parameter (Equation 5) defined by Weber and Chakravorti (1974):

$$X_p = (X_{pmax} \cdot K_L \cdot X_d) / (1 + K_L \cdot X_d) \quad (4)$$

$$R_L = 1 / (1 + K_L \cdot X_{d0}) \quad (5)$$

where X_p is the concentration of element X in the particulate phase at equilibrium (mg kg^{-1}), calculated from the difference in dissolved concentrations between the initial spiked (X_{d0}) and the equilibrium (X_d) concentrations ($\mu\text{g L}^{-1}$, converted to particulate concentrations with the corresponding SPM ratio), X_{pmax} is the maximum charge of X in the SPM and K_L is the constant of Langmuir ($\text{L } \mu\text{g}^{-1}$). Values of R_L indicate the adsorption nature of the isotherm as unfavourable ($R_L > 1$; i.e., highly soluble elements), linear ($R_L = 1$), favourable ($0 < R_L < 1$) and irreversible ($R_L = 0$; i.e., high affinity for the particulate phase; Weber and Chakravorti 1974).

The Freundlich empirical model was the first one to describe heterogeneous (i.e., non-uniform distribution) multilayer adsorption on a non-homogeneous surface (Freundlich 1907). The mathematical expression of the Freundlich isotherm (Equation 6) represents the adsorption intensity by the K_F constant (i.e., the higher the value the higher the affinity for the particulate phase) and the surface heterogeneity with the c value (i.e., the closer to zero the more heterogeneous; Foo and Hameed 2010). When $c = 1$, the relationship between X_p and X_d is linear and $K_F = K_d$ (distribution coefficient).

$$X_p = K_F \cdot X_d^c \quad (6)$$

3. Results

3.1. Tellurium sorption kinetics and isotherms

Sorption kinetics of dissolved Te (Te_{ex}) was rapid (>40% in less than 3 min., Figure 1a) independent from salinity, but highly dependent on the solid/liquid ratios, showing ~90% sorption in 1000 mg L^{-1} SPM within 3 min. Equilibrium between the dissolved and particulate phases was achieved at $\geq 48\text{h}$ in 100 mg L^{-1} SPM and in <5h for 1000 mg L^{-1} SPM (Figure 1a). Experimental blanks (i.e., no SPM) showed no measurable Te_{ex} loss or adsorption onto tube walls throughout the

whole experiment duration. Estimated particulate concentrations were used to calculate partitioning coefficients for Te_{ex} at 48h of adsorption time, showing $\log_{10} K_d$ values in freshwater of $4.94 \pm 0.02 \text{ L kg}^{-1}$ for 100 mg L^{-1} and $5.31 \pm 0.01 \text{ L kg}^{-1}$ for 1000 mg L^{-1} , whereas in seawater K_d values were $4.98 \pm 0.02 \text{ L kg}^{-1}$ for 100 mg L^{-1} and $4.96 \pm 0.09 \text{ L kg}^{-1}$ for 1000 mg L^{-1} .

Sorption isotherms showed non-linear correlations at low SPM concentrations (100 mg L^{-1} , Figure 1b) following a Langmuir isotherm. Langmuir parameters were $K_L = 3.91 \text{ L } \mu\text{g}^{-1}$ and $b = 50.7 \text{ mg kg}^{-1}$ with a separation factor of “favourable” to “very favourable” due to R_L variations between 0.72 and 0.05. Nevertheless, higher SPM content of 1000 mg L^{-1} showed a linear behaviour representative of a Freundlich isotherm (Figure 1c) with relatively low heterogeneity ($c = 1$). The value of $\sim 0.02 \text{ mg kg}^{-1}$ at the intercept represented the inherited Te in the SPM, thus, included in the Te_p concentrations. Calculated Te_p concentrations were in accordance with directly analysed Te_p (<15% difference, within analytical error) from 1000 mg L^{-1} experimental isotherm sediments.

3.2. Selenium sorption kinetics and isotherms

Selenium sorption kinetics (Se_{ex} , Figure 2a) was less rapid than that of Te_{ex} (Figure 1a), showing <10% sorption after 3 min of exposure. There seems to be an effect of both salinity (i.e., higher sorption in seawater) and SPM concentration (i.e., higher sorption in 1000 mg L^{-1}), reaching solid/liquid equilibrium in <24h for 1000 mg L^{-1} with max. 25% sorption. Precise sorption kinetics and equilibrium time for 100 mg L^{-1} (max. 5% sorption) were uncertain, as all Se_d values were close to the experimental blank concentrations with 4% variability shown by the standard deviation. Experimental blanks showed no measurable ^{77}Se loss or adsorption onto tube walls along the experiment. Estimated $\log_{10} K_d$ values at 48h were: $2.51 \pm 0.08 \text{ L kg}^{-1}$ for 100 mg L^{-1} and $2.42 \pm 0.04 \text{ L kg}^{-1}$ for 1000 mg L^{-1} in freshwater, whereas in seawater they were $2.87 \pm 0.10 \text{ L kg}^{-1}$ for 100 mg L^{-1} and $2.57 \pm 0.04 \text{ L kg}^{-1}$ for 1000 mg L^{-1} .

Sorption isotherms for both SPM conditions (100 mg L^{-1} and 1000 mg L^{-1}) showed similar concentrations and linear correlations, representative of a Freundlich isotherm (Figure 2b). The value at the intercept of $\sim 0.26 \text{ mg kg}^{-1}$ represented inherited Se included in the Se_p values. Calculated Se_p concentrations tended to be $\sim 30\%$ higher than those directly measured for 1000 mg L^{-1} SPM isotherm samples.

3.3. Selective extractions

Selective extractions from both freshwater ($S=0$) and seawater ($S=32$) experiments of independent ^{125}Te and ^{77}Se spikes showed differences between spiked and inherited concentrations as well as

distinct fractionation patterns for both elements (Figure 3). Relative contributions of each extracted fraction to total (inherited or spiked) Te and Se concentrations were expressed in percentages (Figure 3). Total concentrations used for Te calculations were 0.05 mg kg⁻¹ for Te_{nat} whereas 2.68 mg kg⁻¹ in S=0 and 3.20 mg kg⁻¹ in S=32 for respective Te_{ex} concentrations. Total Se_{nat} concentrations ranged between 0.37-0.53 mg kg⁻¹ and average Se_{ex} was 25.7 mg kg⁻¹ in both, freshwater and seawater.

The acid-soluble fractions showed the highest Te_{nat} contribution (~50% in F4 and ~30% in F4N, Figure 3a) for freshwater experiments and were 10-20% lower in seawater experiments. Average Te_{nat} contribution was 14% in the H₂O₂ fraction (F3, associated to organic matter), <2% in both, the easily exchangeable or carbonate fractions (F1) and the amorphous Mn/Fe oxide fraction (F2; Figure 3a). In contrast, Te_{ex} sorbed preferentially (average ~60%) to the acid-soluble mineral phases (F4-F4N), comprising amorphous and crystalline Fe and Mn oxides, carbonates, amorphous monosulphurs (e.g., acid volatile sulphides and FeS) and phyllosilicate phases. The latter also implies a ~40% retention of Te_{ex} in the residual fraction. Up to 10% of Te_{ex} was sorbed in the F1-acetate (easily exchangeable or carbonates fraction) and F2-ascorbate (Mn/Fe oxides) extracted fractions, obtaining a lower, <0.2% extraction with the oxidisable fraction (F3-H₂O₂ organic matter and labile/amorphous sulphide phases). In any case, low differences (~5%) were observed between freshwater-adsorbed and seawater-adsorbed Te_{ex} except for acid-soluble fractions where this difference varied from 20 to 30%.

Selective extractions for Se_{nat} showed highest contributions (≥85%) in the F3-H₂O₂ fraction (targeting organic matter and labile/amorphous sulphide phases) of SPM exposed to contrasting salinities (Figure 3b). Acid-soluble fractions obtained from 1M HCl showed 2-fold lower Se_{nat} extractions than 1M HNO₃. Ascorbate solutions extracted concentrations of Se_{nat} similar to that of HCl-extracted aliquots, and the lowest Se_{nat} fractions occurred in acetate extractions (~1%, Figure 3b). Spiked concentrations were also highly extracted in the F3-H₂O₂ fraction, representing 95-105% of total sorbed Se_{ex}. Noteworthy, the second most important fraction was the F2-ascorbate fraction, extracting ~60% of Se_{ex}, presumably from amorphous Mn/Fe oxide mineral phases. This amount of Se_{ex} extracted was higher than that in the acid-soluble fractions F4 and F4N, both extracting ~20% of Se_{ex}. Only 12% of Se_{ex} was leached in the easily exchangeable/carbonate fraction (F1-acetate extraction). Differences between freshwater-adsorbed and seawater-adsorbed Se_{ex} were <10%.

4. Discussion

4.1. Tellurium reactivity and solid fractionation in estuarine salinity and turbidity gradients

Results from sorption isotherms suggest a relatively high Te affinity for the particulate phases, as previously reported for Te radionuclides (Whitehead et al. 1988) and natural Te in the Changjiang Estuary (Wu et al. 2014). The observed log₁₀ K_d values for experimentally adsorbed Te are similar to

typical Te $\log_{10}$ Kd values in the Garonne-Gironde fluvial-estuarine system (Gil-Díaz et al. 2019a) ranging from 4.9 to 5.3 L kg⁻¹. These values are up to one order of magnitude greater than those of natural As (3.5 – 4.8 L kg⁻¹) and Sb (3.8 – 4.8 L kg⁻¹; Gil-Díaz et al. 2018) suggesting that the solubility/mobility of both natural and experimentally adsorbed Te is lower than that of natural As and Sb. Experimentally adsorbed Se showed even lower partitioning (2.4 – 2.9 L kg⁻¹, this study) with ~2 orders of magnitude lower than those of Te, suggesting that Se and Te solubility in environmental matrices may be very different.

Tellurium partitioning may also be compared to that of Cs, given (i) their potential common sources from weathering/remobilisation processes in the watershed (Gil-Díaz et al. 2019a), and (ii) their considerable radioactivity after accidental events (Steinhauser et al. 2014), making them relevant for radionuclide dispersion models. While the observed Te partitioning suggests relatively constant $\log_{10}$ Kd of ~ 4.9 L kg⁻¹, the reported Cs $\log_{10}$ Kd values range from <4.7 L kg⁻¹ in river systems (Ciffroy et al. 2009) to typical values of $\log_{10}$ Kd 5.1 to 6.8 L kg⁻¹ in the Garonne-Gironde fluvial system (Gil-Díaz et al. unpublished). Furthermore, Te $\log_{10}$ Kd values are similar for both freshwater and seawater matrices with a maximum decrease of only 0.3 L kg⁻¹ in the seawater, similar decreases to that observed for Sb in the Gironde Estuary (i.e., 0.2 L kg⁻¹; Gil-Díaz et al. 2018). In contrast, the difference in Cs $\log_{10}$ Kd between freshwater and seawater is 1.4 L kg⁻¹ under experimental conditions (Oughton et al. 1997). Therefore, one would expect only little desorption of Te along estuarine salinity gradients, compared to Cs mobilisation. This major difference in estuarine geochemical behaviour represents important information for the development of continent-ocean transition models anticipating potential Te and Cs radionuclide dispersion after accidental NPP releases. This observation also implies different biological transfers of Te and Cs, depending on the dissolved concentrations and bioaccessible fractions from the particle phase.

Assuming Te adsorption under natural conditions and at natural, low concentrations (i.e. less Te available for adsorption) one would expect the limited Te available to preferentially adsorb onto sites with high binding energy. Under experimental conditions, when relatively abundant dissolved Te exceed the number of strong binding sites, the different Te species would adsorb onto different sites, according to the respective binding strengths, starting with the high binding energy sites. However, the sorption isotherms of dissolved Te onto the particulate phase fits a Langmuir (chemisorption-driven) behaviour for both the low SPM ratio (~100 mg L⁻¹; Figure 1b) and the high SPM condition (1000 mg L⁻¹; Figure 1c), suggesting homogeneous monolayer adsorption of Te at equal bonding energy sites until saturation (Foo and Hameed 2010). This observation implies that, in the present experiment, the amount of dissolved Te available for adsorption did not exceed the number of strong bonding energy sites available, and thus may be representative of sorption processes under natural conditions. This saturation would be achieved at ~50 mg kg⁻¹ for Garonne River SPM which, together with kinetic results suggest that, in the maximum turbidity zone (MTZ) of the Gironde Estuary (SPM ≥ 1000 mg L⁻¹

¹; Sottolichio and Castaing 1999), a hypothetical Te_d concentration of 50 µg L⁻¹ could be retained to ~90% within <3 min. Nearly all Te_d (98%) would adsorb to the SPM in less than 2 h (Figure 1a). However, environmental concentrations of dissolved Te are found within the ultra-trace levels (e.g., Belzile and Chen 2015), and in the case of potential NPP accidents released Te masses would be expected to be orders of magnitude lower than those needed to reach saturation. In fact, a maximum of 68 000 000 Bq m⁻³ of ¹³⁷Cs (equivalent to ~20 ng L⁻¹) has been detected in early April in surface waters adjacent to the FDNPP, decreasing to 10 000 Bq m⁻³ (equivalent to ~3 pg L⁻¹) in early 2012 (Buesseler et al. 2017). Therefore, assuming that the amounts of Te released would be similar in magnitude (or lower) than those of ¹³⁷Cs, nearly all Te_d radionuclides potentially released/produced in the Gironde Estuary would be highly retained in the particulate phase, even in seawater conditions. The latter is in accordance with the scavenged behaviour of Te observed in open ocean profiles of the Pacific and Atlantic Oceans, the East China Sea and the Angola and Panama Basins (Lee and Edmond 1985; Yoon et al. 1990; Wu et al. 2014).

The F4 acid-soluble fraction (attributed to the sum of amorphous and crystalline Fe and Mn oxides, carbonates, amorphous monosulphurs and phyllosilicate phases) is commonly considered to represent the fraction potentially bioaccessible to organisms (Australian and New Zealand sediment quality guidelines; ANZECC and ARMCANZ 2000). Based on this idea, the extractions suggest that ~30% of Te_{nat} in the SPM and ~60% of the experimentally added Te_{ex} retained in the particulate phase would be potentially bioaccessible. Accordingly, these fractions could impact filter-feeding organisms such as economically relevant bivalves (i.e., oysters) with unknown implications for the food chain. Interestingly, this observation also suggests that ~40% of the experimentally adsorbed Te_{ex} could not be recovered by 1M acid extraction, i.e. would be bound to the so-called residual fraction, typically attributed to minerals that are considered as relatively insoluble under respective conditions (Gupta and Chen 1975). Adsorption of Te_{ex} to both, the bioaccessible (60%) and residual (40%) fractions implies interaction with different mineral surfaces, which would not be consistent with the Te_{ex} adsorption isotherm fitting the Langmuir model, unless different fractions showed relatively similar surface properties regarding Te sorption. Differences in Te dissolution between 1M HCl (F4) and 1M HNO₃-based (F4N) extractions (~20% higher in HCl, Figure 3) observed for both naturally and experimentally-adsorbed Te, suggest that HCl may have stronger extraction efficiency than HNO₃, although previous work has reported similar stability and solubility in both HCl and HNO₃ solutions (Inorganic Ventures 2016).

Furthermore, these results appear to be in opposition with the higher Te adsorption observed in SPM in seawater conditions compared to that in freshwater (3.20 vs 2.70 mg kg⁻¹, respectively). In fact, the relatively low acid-soluble extractions obtained from SPM exposed to seawater compared to freshwater conditions suggest that Te binds somehow strongly in seawater conditions (i.e., not related to easily exchangeable binding sites). This observation is in accordance with the observed negative

correlation between the labile fraction of Te_p and the salinity gradient in the Changjiang Estuary (Duan et al. 2014). Nevertheless, further research is required to verify these hypotheses and the specific binding modes of Te to amorphous and crystalline Fe and Mn oxides, amorphous monosulphurs and phyllosilicate phases.

Low extraction of Te_{nat} from the exchangeable/carbonate (<10% in F1), the amorphous Fe/Mn oxide fraction (<10% in F2) and the organic matter fraction (~14% in F3) are consistent with Te_{nat} extractions in marine SPM from the East China Sea (Duan et al. 2014). In fact, Duan et al. (2014) observed 13% and 11% Te in the exchangeable and carbonates fraction (i.e., from an acetate-solution extraction), 11% in the Fe–Mn oxides (i.e., from a hydroxylamine-based solution) and 15% in the organic matter fraction (i.e., from H_2O_2 -solution extraction), leaving ~50% in the so-called “residual” fraction. Similarly, the residual fraction (accounted as the difference between total Te and that in F4) of the Garonne River SPM carried ~50% in freshwater-exposed SPM and 70% in seawater-exposed SPM of Te_{nat} .

For the experimentally adsorbed Te_{ex} simulating potential anthropogenic Te release into the natural environment the results suggest that up to ~99% would be fixed onto SPM within few hours, depending on SPM concentrations. After sediment deposition in the estuarine banks and bed during tidal slacks, the onset of early diagenetic processes might potentially release (i) up to 10% of Te_{ex} due to reductive dissolution of reactive Fe and Mn oxyhydroxides as simulated by ascorbate extractions (F2), and (ii) less than 1% of Te_{ex} adsorbed to organic matter (H_2O_2 extraction, F3). The relatively low F3 fraction obtained for Te_{ex} compared to that of Te_{nat} (14%) may suggest that Te physisorption or chemisorption onto particulate organic matter may be smaller than Te fixation by active incorporation (absorption). The observed results are applicable to Te(VI) sorption behavior, which is assumed to be representative of environmental conditions as Te(VI) is generally more abundant than Te(IV) in aquatic systems (Lee and Edmond 1985; Yoon et al. 1990), representing up to 5-fold the abundance of Te(IV) in the Changjiang Estuary (Wu et al. 2014). The precise Te species released to the environment after a NPP accident are unknown, potentially varying between events due to specific accident conditions. In fact, the presence and concentration of radionuclide species in the nuclear fuel depend on several factors including fuel composition and fuel burnup (Kleykamp 1985). Nevertheless, both Te(IV) and Te(VI) equally adsorb to Fe(III) hydroxides and Te(IV) to illite mineral phases (Harada and Takahashi 2009; Qin et al. 2017). Thus, this work may serve as a preliminary approach to radionuclide Te dispersion fate scenarios in the Gironde Estuary.

In a scenario of Te radionuclide dispersion after hypothetical NPP accidental events the above considerations suggest a dominant role of the estuarine SPM in Te retention and dispersion independent from the hydrological situation. Therefore, relatively few Te radionuclides would be bioavailable strongly limiting potential transfer to the atmosphere due to bio-methylation processes

(Chasteen and Bentley 2003) within the estuarine reaches. Both, relatively low ($\sim 100 \text{ mg L}^{-1}$) and high ($>1000 \text{ mg L}^{-1}$) SPM concentrations would result in almost total sequestration of Te due to adsorption of Te radionuclides on suspended particles. The environmental persistence of Te radionuclides depends on both, half-lives (e.g., ranging between 3.2 days for ^{132}Te to ~ 3 months for $^{127\text{m}}\text{Te}$ for the most relevant ones) and fission yield (i.e., the probability of being produced from nuclear fission reactions). The combination of both parameters may result in estuarine Te radionuclide half-lives of several months. In any case, average particle residence times in the Gironde Estuary (1-2 years, Castaing and Jouanneau 1979), are clearly greater than the aforementioned radionuclide timescales, suggesting that the maximum decay would take place inside the estuary, except for specific hydrodynamic conditions allowing for massive particle expulsion to the coastal ocean (few days per year; Allen et al. 1980; Castaing and Allen 1981). The main decay products are radioactive or stable iodine daughter nuclides (e.g., ^{129}I with $1.57 \cdot 10^7 \text{ y}$ half-life) which will then likely be mobilised to the water column (or pore waters) due to their relatively high solubility.

4.2. Selenium reactivity and solid fractionation in estuarine salinity and turbidity gradients

The experimentally determined sorption of Se onto SPM from the Garonne River is considerably lower than that of Te, in accordance with the mobile character of Se in aquatic systems (Fernández-Martínez and Charlet 2009). The corresponding K_d values ($\log_{10} K_d$ from 2.4 to 2.9 L kg^{-1}) are in the low K_d range of values reported for natural (stable and radioactive) Se in estuarine/coastal systems such as the San Francisco Estuary ($\log_{10} K_d$ of 2.0 – 4.5 L kg^{-1} for 100 mg L^{-1} SPM; Benoit et al. 2010) and 19 Japanese coastal regions ($\log_{10} K_d$ of 2.6 – 3.9 L kg^{-1} ; Takata et al. 2016). In fact, differences between field K_d and experimental K_d for radionuclides have been also observed in environmental SPM samples (e.g., Co, Cs, Mn; Ciceri et al. 1988). These differences were explained by the contribution of the residual fraction to the calculation of field K_d (i.e., total digestions; Ciceri et al. 1988). Furthermore, K_d values are generally site-dependent as SPM mineralogy can strongly control elemental solid/liquid partitioning and Se K_d values have been observed to depend on grain size and organic matter (Takata et al. 2016). Sediments of the Gironde Estuary show characteristic particulate organic carbon (POC) contents ranging from 0.05 to 1.5% (Etcheber et al. 2007; Coynel et al. 2016) and mainly contain silts and some sands (7 - 480 μm ; Coynel et al. 2016).

Marine and estuarine environments generally present higher abundances of Se(VI) over Se(IV) (Cutter 1978; Cutter and Bruland 1984; Guan and Martin 1991). The observed Se(VI) adsorption kinetics fit a pseudo-second order reaction, suggesting that the main process involving Se(VI) removal from the solution are physicochemical interactions (physisorption) with rate-limiting chemisorption surfaces (Robati 2013). This sorption pattern is in accordance with bidentate outer-sphere and monodentate inner-sphere complexes reported for selenate adsorbed on ferric-Fe(III) (hydr-)oxides

and clay minerals like kaolinite (Su and Suarez 2000; Peak and Sparks 2002; Nothstein 2016), despite the higher affinity of selenite (Se(IV)) inner-sphere complexes to these mineral phases (Hamdy and Gissel-Nielsen 1977; Hayes et al. 1987).

Such interactions are relatively weak reflecting the selective extractions results (Figure 3b), as more than half of the acid-soluble fraction (F4) is contributed by exchangeable Se forms (F1). This distribution of Se between several mineral phases is in line with Se(VI) sorption fitting Freundlich isotherms, implying heterogeneous sorption sites. In this case, stronger binding sites are occupied preferentially, decreasing the adsorption energy exponentially as they fill up (Zeldowitsch 1934). Weak interactions between dissolved Se(VI) and particle surfaces could be affected by ionic strength competition, decreasing Se(VI) sorption onto SPM (Su and Suarez 2000). However, the observed differences in Se sorption between freshwater- and seawater-exposed SPM fall within the analytical error.

Co-existing Se(IV) and Se(VI) forms may partly explain differences in parallel selective extractions of Se_{nat} and Se_{ex} . In fact, the selective extraction using oxidising reagents (i.e. the F3-H₂O₂ and the F4N-HNO₃ fractions; Figure 3c,d) generally show a high mobilisation of Se, probably due to the oxidation of Se(IV) to the more mobile Se(VI). Strong oxidants like H₂O₂, used to chemically oxidise the organic matter, as well as HNO₃ compared to HCl, can oxidise Se(IV) from carrier phases other than the target phase (Gruebel et al. 1988). Thus, although high Se content in the organic matter fraction would fit the nutrient type behaviour of Se in marine environments (e.g., Cutter and Bruland 1984, Cutter and Cutter 1995), the fact that the amount of Se extracted by H₂O₂ (F3) is close to 100% could also include Se extracted from other phases by oxidation (Figure 3), implying non-selectivity of the fractionation for Se. Sequential extractions in anoxic biofilms have also identified the non-selectivity of other oxidising reagents (NaOCl) targeting Se in the “organically-associated” fraction for several inorganic/organic Se species (Lenz et al. 2008). The non-selectivity of both, NaOCl and H₂O₂ extractions of Se was already identified for soil and sediment extractions by Gruebel et al. (1988). These observations clearly suggest that commonly applied extraction schemes (e.g., Tessier et al. 1979; Ure et al. 1993) need to be updated and/or adapted before applied to specific elements, such as Se.

It is commonly accepted that the 1M acid-soluble fraction includes mineral phases extracted in the ascorbate fraction, thus trace element concentrations in F4 should be equal to or greater than in F2 fractions (Huerta-Díaz and Morse 1990; Kostka and Luther 1994; Gasparon and Matschullat 2006). The similar Se_{nat} concentrations in both F4-HCl and F2-ascorbate fractions (Figure 3d) are in accordance with this statement, potentially suggesting that most (if not all) of the Se_{nat} in the F4-HCl fraction was extracted from the amorphous Fe/Mn oxide carrier phases (F2-ascorbate fraction). In contrast, Se_{ex} was greater in the F2-ascorbate fraction than in the acid soluble fractions (F4 and F4N,

Figure 3c). Interestingly, this effect of inversed extraction efficiency of parallel selective extractions (F2 vs F4) also occurred for both inherited and spiked Sb in the same SPM from the Garonne River (Gil-Díaz et al. 2019b). Thus, these results suggest an anomaly (compared to more commonly analysed elements such as Cd, Cu, Zn, Pb, etc.) for F2-ascorbate extractions of oxyanions like Se and Sb, but not Te. This effect could be potentially due to strong organic complexation of Se and Sb by the citrate present in the ascorbate solution, thus extracting higher Se and Sb concentrations, independently from the dissolution of the targeted mineral carrier phase (Gil-Díaz et al. 2019b). These observations suggest that reducing conditions and the presence of strong organic ligands, as occurring in sub-oxic early diagenetic conditions (Froelich et al. 1979), potentially enhance Se_{ex} solubility, compared to Se_{nat} .

Re-adsorption of Se (and As) onto non-targeted crystalline Fe hydroxides (i.e., goethite) is favoured during soil and sediment acid-based hydroxylamine extractions (reductive dissolution; Gruebel et al. 1988). Because acid 1M HCl extractions do not dissolve crystalline Fe hydroxides such as goethite and hematite (Raiswell et al. 1994), one cannot exclude Se dissolution from target minerals and re-adsorption onto non-target minerals (e.g. crystalline Fe hydroxides) in 1M HCl and 1M HNO_3 extractions. This effect implies that the estimation of the potentially bioaccessible Se fractions by acid extractions in sediments may be widely biased.

Combining the above findings, one would assume that, after a potential accidental release from NPPs in the Gironde Estuary, the majority of dissolved radioactive Se may be rapidly expelled to the coastal ocean and <30% retention in the particulate phase of the MTZ. Given the similarities between sorption isotherms and K_d at 100 mg L^{-1} and 1000 mg L^{-1} SPM concentrations, dissolved Se probably is dominant for a wide range of SPM concentrations and dissolved radioactive Se releases. Moreover, reducing, suboxic conditions as existing in the MTZ water column (Robert et al. 2004) may further increase Se mobility due to leaching from particles subjected to early diagenetic processes.

Noteworthy, this expected dominance of dissolved Se radionuclides could enhance radioactivity transfer to the biological compartment, given the nutrient behaviour of Se (Tan et al. 2016). In fact, aquatic microorganisms naturally methylate Se as a part of their detoxifying mechanisms (Cooke and Bruland 1987). In the presence of Se radionuclides, bio-methylation processes might produce radioactive volatile Se (e.g., ^{75}Se , ^{79}Se and ^{82}Se) species which must be taken into account for accidental dispersion scenarios. Such Se methylation is a seasonal process (i.e., low in winter and quantifiable in summer) with estimated average fluxes of the order of 10^5 g y^{-1} for the Gironde Estuary (Amouroux and Donard 1997). Such methylation is species-dependent and can potentially show non-negligible atmospheric dispersion (Luxem et al. 2015).

Thus, accidental releases of dissolved Se radionuclides such as ^{75}Se (~119 d half-life), ^{79}Se (~ 10^5 y half-life) and ^{82}Se (~ 10^{19} y half-life) are expected to follow the dynamics of the estuarine water

column (e.g. estuarine water residence times of 10 to 80 days), implying (i) continuous exportation of dissolved radioactive Se to the coast during winter/high discharge conditions, (ii) bio-availability to primary producers and the related food chain, and (iii) potential seasonal production of radioactive methylated species exported to the atmosphere.

5. Conclusion

Batch experiments with bulk SPM and natural freshwater/seawater matrices simulating contrasting estuarine turbidity and salinity gradients showed different sorption kinetics, particulate affinity and solid fractionation distribution for Te and Se. Experimental results strongly suggest that the fluvial-estuarine geochemical cycles of Te and Se are not comparable in terms of reactivity, solubility and bioavailability. Further knowledge on Te speciation and sorption mechanisms is required in environmental studies.

The solid fractionation results suggest that anthropogenic releases of dissolved Te and Se to the aquatic environment do not fully mimic inherited element distribution among SPM mineral phases. The observed differences imply that (i) particulate Te_{ex} is potentially more bioaccessible than the already present particulate Te_{nat} , and that (ii) Se_{ex} may be more easily exchangeable and mobile during early diagenetic processes than Se_{nat} . Comparison of Se solid partitioning with results of selective extractions commonly applied to other trace elements point out to two anomalies: (i) enhanced dissolution of Se species in oxidising conditions probably due to oxidation of Se(IV) to the more soluble Se(VI) and subsequent mobilisation from other solid carrier phases (non-selectivity), and (ii) potential extraction by dissolved organic complexants in addition to release from reducible mineral phases. These findings clearly show that the use of commonly applied extraction schemes to other than originally tested target elements may produce artefacts that need thorough evaluation and must be taken into account for environmental interpretations.

Preliminary dispersion scenarios of hypothetical releases of Te and Se radionuclides into the Garonne-Gironde fluvial-estuarine system suggest high potential adsorption of Te radionuclides onto estuarine SPM in all hydrological conditions (flood and drought). This implies long estuarine residence times for Te radionuclides (up to several months, in accordance with the half-life and activities of the radionuclides released), and the risk of seasonal upstream movement when a hypothetical accident happens in a period when the MTZ is located downstream in the estuary. In contrast, Se radionuclides would preferentially remain in the dissolved phase continuously exported to the coastal ocean within several weeks, implying a risk of transfer to primary producers and the related food chain including seafood.

Figure 1. Sorption of tellurium in natural SPM. (a) Te sorption kinetics (N=3) in freshwater (empty symbols) and seawater (filled symbols) matrices for 100 mg L⁻¹ (triangles) and 1000 mg L⁻¹ (circles) SPM content. Adsorption percentages are calculated as the difference between initial spiking concentration and Te_d at each sampling time. Tellurium isotherms (N=2, after 48h equilibration) for (b) freshwater sorption in 100 mg L⁻¹ and (c) 1000 mg L⁻¹ SPM content, are also shown. Curves and equations correspond to respective fitting regressions. Error bars correspond to standard deviations (SD).

Figure 2. Sorption of selenium in natural SPM. (a) Se sorption kinetics (N=3) in freshwater (empty symbols) and seawater (filled symbols) matrices for 100 mg L⁻¹ and 1000 mg L⁻¹ SPM content as well as (b) selenium freshwater sorption isotherms (N=2, after 48h equilibration) in 100 mg L⁻¹ (triangles) and 1000 mg L⁻¹ (circles) SPM content. Adsorption percentages are calculated as the difference between initial spiking concentration and Se_d at each sampling time. Curves and equations correspond to respective fitting regressions. Error bars correspond to standard deviations (SD).

Figure 3. Parallel selective extractions of Te and Se. (a) Distribution of natural Te (Te_{nat}, N=3), (b) spiked Te (Te_{ex}, N=3), (c) natural Se (Se_{nat}, N=3) and (d) spiked Se (Te_{ex}, N=1) in selective extractions after sorption in freshwater (S=0) and seawater (S=32) conditions. Targeted parallel operationally-defined solid-phase fractions were: F1 – easily exchangeable and/or carbonate fraction (acetate extraction), F2 – reducible Fe/Mn oxides (ascorbate extraction), F3 – oxidisable fraction (H₂O₂ extraction) and F4 – reactive and potentially bioaccessible fraction (HCl 1 M extraction as F4 and HNO₃ 1M extraction as F4N). Percentages represent the extracted concentration in each fraction compared to total particulate concentration. Error bars correspond to standard deviations (SD).

Table 1: Parallel selective extractions as described in Audry et al. (2006).

Sediment fraction	Sample weight (mg)	Reagents	Procedure
F1 – Acetate extraction (easily exchangeable and/or carbonate fraction = carbonates + Mn oxyhydroxydes + sulphates + organic matter)	500	10 ml of sodium acetate (NaOAc, 1 M) + pH adjustment with acetic acid (HOAc, 5 M) during extraction	6 h shaking at 25°C
F2 – Ascorbate extraction (reducible Fe/Mn oxides = Mn oxides and amorphous Fe oxides)	200	12.5 ml ascorbate solution (pH = 8)	24 h shaking at 25°C
F3 – H ₂ O ₂ extraction (oxidisable fraction = organic matter and labile/amorphous sulphides)	500	2.5 ml H ₂ O ₂ 30% (at pH 5 with NaOH) + 1.5 ml H ₂ O ₂ 30% + 2.5 ml ammonium acetate (1M)	2 h + 3 h at 85°C + 30 min shaking at 25°C
F4 – acid soluble HCl extraction (and complementary F4N – HNO ₃ extraction) (reactive and potentially bioaccessible = amorphous and crystalline Fe/Mn oxides + carbonate fractions + amorphous monosulphurs + phyllosilicates)	200	12.5 ml HCl or HNO ₃ (Suprapur®, 1 M)	24 h shaking at 25°C
