ABSTRACT

Objective: This study aimed to investigate the relationship between changes in clinical status on daily life physical activity (PA) in patients with idiopathic inflammatory myopathy (IIM).

Methods: Patients with dermatomyositis (DM), immune-mediated necrotizing myopathy (IMNM) or overlap myositis (OM) who presented either a new-onset or relapsing IIM, stable disease on maintenance therapy or were undergoing immunosuppressant tapering were included. Patients were evaluated at inclusion (V0), and at two follow-up visits (V1, 94±12 days from V0; V2, 96±17 days from V1). The American College of Rheumatology/European League against Rheumatism (ACR/EULAR) response criteria was recorded. PA assessed using 14-days raw accelerometry data gathered using a wrist-worn accelerometer after each visit (mean daily Euclidean norm minus 1 g (ENMO) was computed).

Results: Fifty-five patients (16 OM, 27 IMNM and 12 DM) were included. At baseline, 67% of patients had an ENMO Z-score less than 1. At inclusion, ENMO mainly correlated with health assessment questionnaire score (HAQ, $\rho=-0.51$, $p<0.01$), manual muscle testing 8 (MMT8, $\rho=0.42$, $p<0.01$), creatinine level ($\rho=0.41$, $p<0.01$), and SF-36 physical functioning score ($\rho=0.38$, $p<0.002$). At follow-up, ENMO changes mainly correlated with changes in MMT8, HAQ, SF-36 fatigue, and depression score (all $\rho>0.43$, all $p<0.001$). Level of agreement between ACR/EULAR response criteria and changes in PA was 15, 45, and 90% for minimal ($n=13$), moderate ($n=20$), and major ($n=10$) improvements, respectively.

Conclusion: Baseline PA levels and change in PA correlated with muscle strength and function, yet changes in PA were also influenced by psychological status. Only patients with major improvements on the ACR/EULAR criteria had significant increase in PA. Accelerometer may serve as an objective tool to define a clinically relevant real-life outcome.

Introduction

Idiopathic inflammatory myopathies (IIM) are a very heterogeneous group of autoimmune muscle diseases impairing patients' quality of life [1]. They can be classified into four main subsets: dermatomyositis (DM), immune-mediated necrotizing myopathy (IMNM), overlap

myositis (OM) and inclusion body myositis (IBM) [2]. Heterogeneity within each subset is related to the variability of muscle involvement (weakness severity, dysphagia, heart or respiratory muscle involvement) and extra-muscular features. Thus, IIM assessment in clinical practice and in the design of clinical trials remains challenging. Improving management requires reliable tools to assess disease activity and evaluate the impact of IIM impact on quality of life. Novel tools are crucial not only for improving patients' management in clinical practice but also for assessing new therapeutic options in clinical trials.

The International Myositis Assessment & Clinical Studies Group (IMACS) developed a core-set measure (CSM) to capture both

¹ These authors contributed equally to this work

muscular and/or extra-muscular disease activity in IIM [3]. The CSM includes: a manual muscle testing (MMT), muscle enzymes, Health Assessment Questionnaire (HAQ), a physician global disease activity, a patient global disease activity, and one item is specifically developed to assess the extra-muscular involvement (extra-muscular global disease activity). Using these CSM, the American College of Rheumatology/European League against Rheumatism (ACR/EULAR) recently developed criteria for clinical response in IIM based on the absolute percent change of the CSM between two time-points [4].

Yet, clinical meaningfulness of this clinical response (mild, moderate and major) in patients' daily life remains to be determined. Muscle weakness may alter functional abilities of patients with IIM and therefore impact their daily physical activity (PA). Moreover, daily PA may also be affected by the cardiorespiratory state, pain level, extra-muscular features, as well as psychological and behavioral components. Analysis of raw multiday wrist-worn triaxial accelerometers data using open-source tools [5,6] has been identified as an efficient way to objectively quantify PA. We used this approach in a recent pilot study and highlighted that clinical changes were associated with changes in PA in patients with IIM [7,8]. However, the complex interplay between changes in clinical/biological outcomes and changes in real-life PA remains unknown.

The aim of this study was therefore to investigate relationships between PA levels, changes in PA levels, and IMACS CSM and ACR/EULAR response criteria in patients with IIM.

Materials and Methods

Study design

A prospective single center study was performed at our national adult referral center for neuromuscular diseases. All patients were adults and were evaluated as part of routine clinical care at the outpatient clinic or during hospitalization at inclusion (V0, from February 2017 through April 2018). Patients were re-evaluated during two follow-up visits, (V1, 94±12 days from V0; V2, 96±17 days from V1).

Participants

Included patients were classified with an IIM according to the 2017 EULAR/ACR classification criteria [9] and were further divided into four subgroups: DM, IMNM (European NeuroMuscular Center criteria) [10], or an OM, including anti-synthetase syndrome [11,12]. Patients with IBM [13] were not enrolled, since standard immunosuppressive therapy has not been shown to improve the disease course [14] and the ACR/EULAR clinical response criteria was not designed for this IIM subgroup. Patients were enrolled at disease onset, during a relapse, or those with stable disease, either on maintenance therapy or while undergoing immunosuppressant tapering.

Myositis-specific and myositis-associated antibodies testing was recorded at the time of myositis diagnosis and was performed using line blot commercial assay (EUROIMMUN, Lübeck, Germany) and included: anti-SAE, -TIF1 γ , -NXP2, -MDA5, -Mi-2, -Jo1, -PL-12, -PL-7, -SRP, -OJ, -EJ. Anti-HMGCR antibodies were identified using ELISA (Inova Diagnostics Inc.) or addressable laser bead immunoassay (ALBIA).

Muscle disease assessment

Muscle tests

Muscle strength was assessed using the MMT-8 (8 muscle groups, 10-point Kendall scale) [15]. MMT of the psoas was performed but was not used to compute the MMT-8 total score. Quantitative muscle strength of the deltoid (i.e. shoulder abduction) and psoas (i.e. hip flexion) was performed using a hand-held dynamometer (HHD) (MicroFet2TM; Hoggan Health Industries, USA) following

standardized procedures [16] and expressed as absolute values and as percentages of predicted values, using previously published equations [17].

Additionally, endurance assessments were performed in the upper limbs and the lower limbs as previously reported [18]:

- Barré test: time in seconds (sec) during which a patient can maintain his arms in flexion at a 90° angle with completely extended elbows. The value is set to 240 if the duration exceeds 240 s.
- Mingazzini test: time in second during which a patient can maintain the legs elevated with the hips and the knees bent at a 90° angle, in the supine position. The value is set to 100 if the duration exceeds 100 s.

All muscle assessments were performed by the same trained clinician (OLC). Physician and patient global disease activity using a 10-cm visual analog scale (VAS), serum creatine kinase (CK, normal range = 22–198 IU/L), aspartate aminotransferase (AST, normal range = 6–34 IU/L), alanine aminotransferase (ALT, normal range = 7–55 IU/L), lactate dehydrogenase (LDH, normal range = 140–280 IU/L) and creatinine levels (normal range = 62–106 μ mol/L), and HAQ were also assessed at each visit.

Physical activity assessment

Physical activity monitoring and data collection. PA was assessed using a widely-used wrist-worn accelerometer (GENEActiv[®], Activinsights Ltd, Kimbolton, UK), which was worn on the non-dominant wrist of patients at all time (e.g. day, night, shower) for 14 consecutive days after each visit. This duration has been demonstrated as a comfortable time window to capture daily PA [19,20].

The GENEActiv accelerometers measure triaxial movement acceleration in gravity units ($1g = 9.81 \text{ m/s}^2$) at a frequency of 50 Hz. Participants continued their daily life and no instructions were provided to patients regarding both structured and spontaneous PA. At each patients' visit, participants were asked to estimate (i.e. number and duration of sessions per week then analyzed as minutes per week) any structured PA (e.g. exercise training, gymnastics, swimming) and/or physical therapy sessions they have been performing within 2 weeks prior to each visit.

Processing of raw accelerometer data. Following the measurement period, raw accelerometer data were extracted using the manufacturer software and processed using the open-source GGIR R-package [<https://cran.r-project.org/web/packages/GGIR>] [5,6]. To ensure different devices provided a similar output under similar conditions, the acceleration signals to local gravity were calibrated using the procedure described by van Hees et al. [5]. The Euclidean distance is the straight-line distance between two points in Euclidean space forming a metric space and the associated norm is called the Euclidean norm measuring the length of the vector. The vector magnitude from the three axes corrected for gravity referred to as Euclidean norm minus 1 g (gravitational constant) (ENMO) was calculated [5]. This procedure allows for processing the raw acceleration data and attempting to separate the movement and gravitational components of the signal [6]. ENMO is presented in milli-g (mg with $1 \text{ mg} = 0.00981 \text{ m/s}^2$) per day. The procedure for non-wear detection was performed as previously described [6]. Minimal worn time per days for day-specific analyses was set at 16 h. Duration of inactivity, light PA, and moderate to vigorous PA were computed using previously validated thresholds [21]: inactivity <30 mg; $30 \text{ mg} \leq$ light PA < 100 mg; $100 \text{ mg} \leq$ moderate PA < 400 mg; vigorous PA $\geq$ 400 mg. Moderate to vigorous activity accumulated in $\geq$ 10 min bouts for which 80% of the epochs are above 100 mg was also calculated. ENMO Z-scores accounting for age and sex were computed based on accelerometer measured PA in over 100,000 participants within the

UK Biobank study [22]. ENMO Z-scores were used to assess PA levels in IIM patients at inclusion compared to healthy population.

Extra-muscular disease assessment

The extra-muscular disease activity VAS, a quality of life questionnaire (SF-36 version 2) [23] and the Hospital Anxiety and Depression scale (HAD) [24] were completed at each visit.

ACR/EULAR IIM response criteria

As per the ACR/EULAR response criteria, a total score change of <20 , ≥ 20 , ≥ 40 or ≥ 60 was considered as an unchanged, minimal, moderate or major improvement, respectively [4]. In addition, improvement scores were calculated for each CSM [4] as well as absolute percent changes for all recorded variables. For the purpose of statistical analysis only, patients with CSM negative CSM scores were also taken into account to compute worsening clinical status. An adapted ACR/EULAR worsening criteria was defined as follows: $-40 \leq$ minimal worsening ≤ -20 ; $-60 \leq$ moderate worsening ≤ -40 ; ≥ -60 major worsening.

Statistics

Quantitative variables are reported as mean $\pm$ standard deviation or mean (95% confidence interval [lower 95% CI, upper 95% CI]). One-way ANOVAs were conducted to investigate difference between IIM subgroups at inclusion in normally distributed variables. Bonferroni's post-hoc tests were performed if ANOVAs demonstrated a significant main effect of subgroups on variables. Repeated measure ANOVAs were used to investigate changes at follow-up with Bonferroni's post-hoc tests in normally distributed variables. Friedman test with Bonferroni's post-hoc tests were used in non-normally distributed variables. Cohen's *d* effect sizes were also computed to compare differences between subgroups (e.g. as defined by the ACR/EULAR response criteria). To assess inter-week reliability of ENMO, change in mean and paired *t*-tests were used for detection of systematic bias. Standard error of measurement was used to study absolute reliability. Relative reliability was assessed with the intra-class correlation coefficient with 95% confidence interval. Regression analysis and Bland–Altman plots were also performed. Least significant change for ENMO was defined as twice the standard error of measurement between mean ENMO of the first and second week from all available recordings. Least significant change for ENMO was used to classify changes in PA. Categorical variables were compared using a χ^2 . Kappa statistic was used to test for agreement of the adapted ACR/EULAR status and changes in PA (for this analysis, the adapted ACR/EULAR status was simplified to impaired, unchanged, improved) Potential relationships between variables were investigated using Spearman correlation coefficient. For investigating relationship between changes in PA and changes in other variables, changes between V0 and follow-up visits (V1, V2) were analyzed jointly. Random forest regression analysis was also used to identify most important variable influencing PA at baseline and changes in PA at follow-up. For all statistical analyses, $p < 0.05$ was considered significant. All statistical analyses were performed in R 3.4.3 Team RC. R: A Language and Environment for Statistical Computing. 2017.

Ethics statement

The study conformed to the Declaration of Helsinki and was approved by local Ethics Committee (CPP Ile-De France VI (2013–12–19), CCTIRS (N°14.323) and CNIL (915,139)) for the use of medical information recorded in the IIM database for scientific purposes. All participants gave written informed consent.

Results

Participants

Fifty-nine patients were enrolled, and four patients were excluded either because they were lost to follow-up ($n = 3$) or because they failed to perform $\geq 2/3$ accelerometer recordings ($n = 1$). The characteristics of the 55 included patients (12 DM, 27 IMNM and 16 OM) are presented in Table 1. Myositis-specific antibodies were anti-TIF1-gamma ($n = 4$), -NXP-2 ($n = 3$), -Mi-2 ($n = 1$), -SAE ($n = 1$) in DM; anti-HMGCR ($n = 18$), -SRP ($n = 7$) in IMNM; and anti-Jo1 ($n = 4$), -PL7 ($n = 1$), -EJ ($n = 1$) in OM. Most patients were treated with a combination of corticosteroids and immunosuppressants, with or without intravenous immunoglobulin. Three patients had a combination of rituximab with either methotrexate ($n = 2$) or mycophenolate mofetil ($n = 1$).

Patients with IMNM presented a longer disease duration and lower extra-muscular global involvement compared to the other subsets and a poorer SF-36 social functioning, physical role, emotional role and emotional wellbeing compared to patients with DM (Table 1). On average, baseline quantitative muscle strength, expressed as a percentage of predicted strength, was reduced in psoas and to a lesser extent in deltoids. Consistently, endurance (Barré and Mingazzini tests) measured at baseline was largely reduced in the lower limbs and was less importantly affected in the upper limbs. Variable values and changes at inclusion and follow-up visits are displayed in Table 2.

Assessing physical activity with wrist-worn accelerometer is feasible and reliable in patients with IIM

Wear-time compliance of triaxial wrist-worn accelerometers was 13.7 ± 1.1 days. There was no change in wear-time compliance between time points ($p = 0.87$). Number of valid week days was 9.8 ± 0.8 (maximum of 10 days) and number of valid weekend days was 3.9 ± 0.3 (maximum of 4 days). Of note, no calibration error (i.e. estimated based on all 'non-movement' periods in the measurement after applying the autocalibration) was reported. Non-wear time expressed as a percentage of total measurement duration was $0.12 \pm 0.53\%$. Standard error of measurement expressed as a percentage was 10.01 [8.97, 11.32]% and intraclass correlation coefficient > 0.9 . Inter-week reliability of ENMO is displayed in Fig. 1A. ENMO least significant change was 4.10 mg/day.

Low physical activity in most patients with IIM compared to the general population

PA metrics at baseline are shown in Fig. 1. Fifty-four percent of patients had a Z-score between -1 and -2 and 12% had Z-score < -2 . There was no significant difference in PA metrics across disease subgroups (all $p > 0.16$). PA intensity was similar in all subsets and was largely dominated by light PA (average 193 ± 74 min/day), while moderate to vigorous PA was only performed on average performed only 6 ± 15 min/day. Average duration of physical therapy sessions and self-structured PA was 33 ± 66 and 14 ± 40 min/week, respectively. There was no correlation between ENMO and physical therapy or structured PA (both $p > 0.19$).

At inclusion, physical activity correlates with muscle strength and patients reported outcome of physical function

Relationships between PA and variables at inclusion (V0) are shown in Table 3. Variables significantly correlated with ENMO Z-score at V0 are displayed in Fig. 2. At V0, ENMO mainly correlated with the HAQ, MMT8, creatinine levels, and SF-36-physical functioning. Interestingly, the other variables included in the CSM were not correlated with ENMO (physician-reported global disease activity,

DM, dermatomyositis; IMNM, immune mediated necrotizing myopathy; OM, overlap myositis; Yr, year; MAA myositis-associated antibodies; MSA, myositis-specific antibodies; CK, creatine kinase; IVIg, intravenous immunoglobulin; MMT8, manual muscle testing 8; HHD, hand held dynamometry; HAQ Health Assessment Questionnaire; HAD, Hospital Anxiety and Depression scale; SF-36, Short Form Health Survey; Bonferroni's post-hoc tests were performed if ANOVA demonstrated significant main effect of subgroups on normally distributed variables; Dunn's post-hoc tests were performed if Kruskal-Wallis test demonstrated significant main effect of subgroups in non-normally distributed variables * significant difference between IMNM and OM

[#] significant difference between IMNM and DM, \$ significant difference between DM and OM. Except for SF-36 variables,% indicates proportion/prevalence.

patient-reported global disease activity, muscle enzymes and extra-muscular disease activity).

According to random forest regression, most important features associated with ENMO Z-scores were also the HAQ, MMT8, creatinine levels, and SF-36-physical functioning (i.e. relative predictor importance was 1.0, 0.66, 0.66, and 0.80, respectively).

At follow-up, changes in physical activity metrics correlates with changes in muscle strength, patients reported outcome of physical function and depression score

Values and changes in variables at follow-up are displayed in Table 2. Relationships between PA and variables at follow-up are shown in Table 3. Variables significantly correlated to absolute changes in ENMO at follow-up are displayed in Fig. 3. At follow-up, changes in ENMO mainly correlated with ACR/EULAR response criteria, changes in HAD-depression, HAQ, SF-36 fatigue, and MMT8.

Interestingly, all the variables included in the CSM were significantly correlated with changes in ENMO.

According to random forest regression, the most important features associated with changes in ENMO were absolute percent changes in physician global disease activity, CK/ALT/AST levels, MMT8, SF-36-energy/fatigue, HAQ, SF-36-physical functioning, and HAD-depression (i.e. relative predictor importance was 1.0, 0.99, 0.95, 0.85, 0.95, 0.85, 0.83, 0.78, and 0.76, respectively).

Only major improvement of the ACR/EULAR response criteria is strongly associated with significant increase in physical activity

Using the least significant change in ENMO (>4.10 mg/day) at follow-up, we observed that: 8.8% of patients had lower PA, 66.6% of patients had unchanged PA, and 26% of patients had increased PA. Using our adapted ACR/EULAR response criteria, 2.2% of patients had moderate worsening, 2.2% of patients had minimal worsening,

ENMO, Euclidian norm minus one; HAQ Health Assessment Questionnaire; CK, creatine kinase; IVIg, intravenous immunoglobulin; MMT8, manual muscle testing 8; HDD, hand held dynamometry; HAD, Hospital Anxiety and Depression scale; SF-36, Short Form Health Survey; IVIg, intravenous immunoglobulin; Bonferroni's post-hoc tests were performed if repeated measures ANOVA demonstrated significant main effect of time on normally distributed variables (*, **, $p < 0.05$, $p < 0.001$, respectively); Bonferroni's post-hoc tests were performed if repeated Friedman test demonstrated significant main effect of time on non-normally distributed variables (*, **, $p < 0.05$, $p < 0.001$, respectively). Δ V1 and Δ V2, changes expressed as absolute percent change ([final value − baseline value] / range × 100) or absolute changes (see manuscript for details). Except for SF-36 variables, % indicates proportion/prevalence.

47.7% had unchanged status, 14.4% had minimal improvement, 22.2% had moderate improvement, and 11.1% had major improvement.

Agreement between the adapted ACR/EULAR response criteria and change in PA at follow-up is shown in Table 4. All patients with a worsened ACR/EULAR clinical status had unchanged PA. Unchanged ACR/EULAR clinical status was associated with unchanged PA. Level of agreement between ACR/EULAR status and changes in PA was associated with the degree of improvement, i.e. agreement was low (15%) for minimal improvement, mild (45%) for moderate improvement, and high (90%) for major improvement. The Cohen's kappa was 0.32 ($p < 0.001$), which represents fair agreement according to Ashby et al. [25] classification.

We subsequently investigated differences in patients with moderate ACR/EULAR improvement with unchanged or increased PA. At follow-up, patients with unchanged PA had lower ACR/EULAR total score ($43.9 \pm 3.0\%$ vs. $50.0 \pm 6.0\%$, $p < 0.01$, $d = -1.28$), smaller changes in psoas HDD strength ($9.7 \pm 9.0\%$ vs. $21.1 \pm 6.4\%$, $p < 0.01$, $d = -1.46$), smaller changes in muscle enzymes (ALT: $-12 \pm 22\%$ vs. $95 \pm 87\%$, $p < 0.05$, $d = 1.29$; AST: $-14 \pm 28\%$ vs. $-122 \pm 125\%$, $p < 0.05$, $d = 1.18$; LDH: $5 \pm 19\%$ vs. $-133 \pm 106\%$, $p < 0.05$, $d = 1.81$), smaller changes in HAD depression score ($-4 \pm 8\%$ vs. $-15 \pm 10\%$, $p < 0.05$, $d = 1.26$), and

smaller changes in SF-36-energy/fatigue scores ($12 \pm 12\%$ vs. $32 \pm 23\%$, $p < 0.05$, $d = -1.09$). Interestingly, no significant difference was found for change in the extra-muscular disease activity (-10 ± 10 vs. -4 ± 7 , $p = 0.19$). Patients with unchanged PA at follow-up presented at inclusion a lower ENMO Z-score (-1.3 ± 0.0 vs. -0.66 ± 0.75 , $p < 0.05$, $d = -1.21$), lower percentage predicted psoas strength ($50 \pm 5\%$ vs. $63 \pm 11\%$, $p < 0.05$, $d = -1.58$), lower ALT/AST/LDH levels (all $p < 0.05$), longer disease duration (5.0 ± 1.7 years vs. 1.9 ± 1.9 years, $p < 0.05$, $d = 1.74$), poorer SF-36-emotional wellbeing and energy scores (all $p < 0.05$), higher extra-muscular disease activity (2.8 ± 1.1 vs. 1.1 ± 1.1 , $p < 0.05$, $d = 1.57$), and lower patient-reported global disease activity (3.6 ± 1.3 vs. 6.4 ± 3.0 , $p < 0.05$, $d = -1.21$).

Discussion

Our study demonstrates that most patients with IIM display low PA compared to age-matched healthy individuals in the general population, highlighting the burden of IIM on patients' daily life. Muscle strength and patient reported physical function were major determinants of PA at inclusion and follow-up. However, PA change was also associated with change in depression and fatigue levels. At follow-up, all patients with worsened or unchanged clinical status

Fig. 1. Physical activity metrics at inclusion

Bland–Altman plot and regression analysis of Euclidian norm minus one (ENMO) during the first and second week of recordings (wk1 and wk2, respectively; Panel A). In the Bland–Altman plot, the solid line indicates the mean difference between the measurements and the dashed lines represents the limits of agreement. In regression analysis, the dashed line represents the identity line, and the solid line indicates the linear regression line with shaded 95% confidence region. Physical activity metrics at baseline (Panel B).

had unchanged PA. Most patients (90%) with a major improvement (as defined by the ACR/EULAR response criteria) had a significant increase in PA, whereas PA increase was observed in only half of the patients with a moderate improvement. Few patients with a minimal improvement displayed a significant increase in PA.

Our data demonstrate that monitoring PA using wrist-worn accelerometers is feasible in patients with IIM (nearly negligible non-wear time) [26–28] and display excellent absolute and relative reliability as previously demonstrated in patients cohorts with other conditions [20,29,30].

Dependent variable was ENMO Z score at inclusion and changes in ENMO at follow-up; MMT8, manual muscle testing 8; HAQ Health Assessment Questionnaire; CK, creatine kinase; AST, aspartate transaminase; ALT, alanine transaminase; LDH, lactate dehydrogenase; HDD, hand held dynamometry; SF-36, Short Form Health Survey; HAD, Hospital Anxiety and Depression scale. * changes expressed as absolute percent change [(final value – baseline value) / range × 100] or absolute changes (see manuscript for details).

Fig. 2. Significant relationships between physical activity and other variables at inclusion

Significant correlations ordered from top left to lower right according to strength of association as computed using Spearman's correlation (ρ). HAQ Health Assessment Questionnaire; MMT8, manual muscle testing 8; creat, creatinine; SF-36, Short Form Health Survey; SF-36-phys, SF-36 physical functioning; Hb, hemoglobin; HHD, hand held dynamometry; ENMO Z-score, Euclidian norm minus one expressed as a Z-score.

PA was associated with objective muscle disease measures (MMT8, HHD, endurance, creatinine level) as well as patient-reported outcomes (general health as assessed by the HAQ, functioning capacities and pain as assessed using the SF-36 questionnaire, see Fig. 2). Some variables (e.g. MMT8, Barré, Mingazzini) displayed ceiling and/or floor effects in many patients. Consequently, and although non-parametric tests were used, correlations between PA and the latter variables must be interpreted with caution.

At follow-up, change in PA correlated with MMT8 total score and accordingly, with clinical status change (ACR/EULAR response criteria). This may be explained, at least in part, by the fact that the ACR/EULAR response criteria include many of the variables correlated to PA at baseline. The agreement between change in PA and ACR/EULAR status was excellent when major improvement occurred suggesting that patients captured in this category correspond to patients with a clinically meaningful improvement (i.e. translating to significant change in PA). Yet, only a half of patients with a moderate improvement had an increase in PA, suggesting that this ACR/EULAR category captures a heterogeneous group of patients associated with and without significant change in PA. A potential explanation is that mild improvement in the MMT8 score may be overlooked as physicians have difficulty discriminating most Medical Research Council categories (5-points scale) especially for mild variations [31]. In addition, small increase in muscle strength does not necessary translate into

substantial improvements in functional abilities [32]. We also stress that PA was monitored continuously for 2 weeks in real life suggesting that this measure may be more reliable to capture changes than a one point-in-time evaluation point at a medical visit. As only 10% of patients with minimal improvement displayed changes in PA, it suggests that this ACR/EULAR category defines a homogeneous group of patients with very low probability of presenting a significant change in PA. Altogether, these findings suggest that an increase in PA > 4.10 mg/day (i.e. defined as the least significant change) could serve as a useful, feasible, and objective tool to define a clinically relevant real-life outcome.

Predictors of mismatch between ACR/EULAR response criteria and change in PA were smaller change in muscle strength and muscle enzymes. Interestingly, our data also suggest that disease duration and long-term damage may prevent patients from displaying an improved PA, as longer disease duration and lower patient-reported global disease activity were predictors of unchanged PA. The extra-muscular disease activity was not a predictor of mismatch in our study, suggesting that the absence of increase in PA in patients with ACR/EULAR moderate improvement is not explained by active extra-muscular features. We acknowledge that we were unable to fully address the importance of each extra-muscular features individually and their possible impact on PA behavior (pain related to arthritis, shortness of breath related to lung involvement). Another limitation

Fig. 3. Significant relationships between changes in physical activity and changes in other variables at follow-up

The x-axis represents the absolute change in Euclidian norm minus one (ENMO). The y-axis represents changes in variables (Δ). Shapes indicate first and second follow-up visits (V1, V2). ACR/EULAR, American college of rheumatology/European league against rheumatism; ACR/EULAR total score, sum of absolute percent change in core-set measures; ACR/EULAR status, patient status according to the adapted ACR/EULAR response criteria (−2, moderate worsening; −1, minimal worsening; 0, unchanged; 1, minimal improvement; 2, moderate improvement; 3, major improvement; see manuscript for more details). HAD, Hospital Anxiety and Depression scale; HAQ Health Assessment Questionnaire; SF-36, Short Form Health Survey; MMT8, manual muscle testing 8; GA, global assessment; AST, aspartate transaminase; CPK, creatine phosphokinase; ALT, alanine transaminase; HHD, hand held dynamometry; creat, creatinine; Struct PA, structured physical activity; ExtramusGA, extra-muscular global assessment.

Table 4

Table of contingency of agreement between adapted ACR/EULAR response criteria and change in PA at follow-up.

Adapted ACR/EULAR status*	Change in ENMO decreased	unchanged	increased	% match
Moderate worsening	0	2	0	0
Minimal worsening	0	2	0	0
Unchanged	6	34	3	79
Minimal improvement	1	10	2	15
Moderate improvement	1	10	9	45
Major improvement	0	1	9	90

ACR/EULAR, American college of rheumatology/European league against rheumatism. Definition of worsening clinical status were also computed by adapting the original definitions as follow: $-40 \leq$ minimal worsening ≤ -20 ; $-60 \leq$ moderate worsening ≤ -40 ; ≥ 60 major worsening. gray boxes indicate expected match.

is that we cannot exclude the impact of active DM skin rash on PA behavior as cutaneous disease activity is associated with poorer quality of life [33].

Another important point is the negative impact of wellbeing and emotional variables on PA behaviors suggested by smaller changes in depression score and fatigue level that were also predictors of mismatch between ACR/EULAR response criteria and change in PA. PA is not only influenced by physical/physiological factors but also by behavioral, demographic, and socioeconomic factors [34,35]. Our data show that change in HAD depression score was correlated to change in PA in accordance with previous data demonstrating the association between PA and mental health [30,31]. This observation highlights the importance of considering mood/psychological disturbances when patients with IIM present with lower than expected PA level when disease activity is improving. Psychotherapeutic interventions such as patient-centered cognitive behavioral therapy may contribute to promote more active lifestyle and thus, improve outcomes and reduce comorbidities associated with poor mental health and physical inactivity. Socioeconomic events (e.g. relocation, change in social environment) are very likely to affect PA and should be recorded in such studies. PA assessment must be highly contextualized and not considered as a unique tool for disease activity monitoring, especially for patients with predominant extra-muscular involvement. We also acknowledge that most of our patients were recruited in a stable state and that these acquisitions remain to be evaluated in a clinical trial.

To conclude, this study demonstrated that significant increase in PA occurs in most patients with major improvement (as defined by ACR/EULAR IIM response criteria), in only half of the patients with moderate improvement, and almost never in patients with mild improvement. We also identified that significant increase in PA in patients with clinical improvement is less likely to occur in the absence of improvement in psychological status.

Altogether, our data support objective assessment of PA in future prospective clinical trials and clinical practice to improve the assessment of intervention and clinical management of patient with IIM.
