Focusing on speech processing, we illustrate how this framework leads to new hypotheses.</p>

Highlights

- We review research on temporal predictions (particularly in auditory contexts) and consider how recent empirical evidence challenges standard oscillatory entrainment models.
- Top-down phase resetting mediated by the motor system or higher order language or attention related systems facilitate bottom-up perceptual processing.
- A model that considers neuronal oscillations as intrinsic temporal constraints (rather than subserving a specific function) and incorporates top-down phase resetting is suggested as a parsimonious solution for both periodic and aperiodic temporal predictions.
- Assuming that temporal predictions prospectively control oscillatory constraints, the proposed perspective sets a new frame for the interpretation of neurophysiological responses to auditory and speech streams.

Proactive sensing of periodic and aperiodic auditory patterns

Abstract

The ability to predict when something will happen facilitates sensory processing and the ensuing computations. Building on the observation that neural activity entrains to periodic stimulation, leading neurophysiological models imply that temporal predictions rely on oscillatory entrainment. While they provide a sufficient solution to predict periodic regularities, these models are challenged by a series of findings that question their suitability to account for temporal predictions based on aperiodic regularities. Aiming for a more comprehensive model of how the brain anticipates “when” in auditory contexts, we emphasize the capacity of motor and higher order top-down systems to prepare sensory processing in a proactive and temporally flexible manner. Focusing on speech processing, we illustrate how this framework leads to new hypotheses.

1 Temporal predictions in auditory contexts

We extract **temporal regularities** from the sensory environment to anticipate upcoming events. Although there exists an infinite number of possible temporal patterns or cues that one can exploit for prediction, the **periodic** (isochronous, often informally referred to as **rhythmic**; see glossary) occurrence of a sound is perhaps the first regularity that comes to mind. The human brain is captivated by periodic streams, and human listeners –as well as **some** other species– seem compelled to synchronize gestures to predictable rhythmic beats [1]. One possible explanation of this drive is that proactively ‘**tracking** the future’ optimizes processing of incoming information and the adaption of behavior [2]. The majority of existing data **is** compatible with the notion that the **entrainment** of neural activity to periodic stimulations is instrumental to sensory selection, facilitating the processing of events that occur around the entrained, and therefore expected beat [3]. Although periodicity is the most obvious form of temporal regularity and is used in various sonic contexts (**speech**, music), limiting the scope of temporal processing to this type of pattern (or studying it in isolation from other types of patterns) biases and restricts the generalizability of current models. **Speech**, for instance, contains quasi-periodic energy fluctuations at the syllabic rate [4]. However, aperiodic cues, such as provided by syntactic or semantic information, can also be used to predict upcoming speech events, e.g. the pauses that typically follow prepositional phrases [5]. Although generally periodic, music often contains aperiodic but trackable, regular meter at the beat or subdivision level, as featured in music from the Balkan or Africa, amongst others [6]. Whether there exists a principled reason to assume different neuronal mechanisms for periodic compared to other types of regularities is unclear. At any rate, invoking multiple models to account for the same process comes at the expense of **parsimony**.

We briefly review the main results that have contributed to neuronal (oscillatory) entrainment (Box 1) as the mainstream mechanistic explanation for periodic temporal predictions. We then argue that recent evidence of perceptual facilitation by aperiodic predictions [7,8] is not compatible with classical models of oscillatory entrainment. **Crucially**, we suggest that this tension calls for a new model of how temporal predictions **modulate** intrinsic oscillations to enhance sensory processing. First, we **advance the view that** neuronal oscillations constitute a ‘processing **constraint**’ (Box 2) rather than a specific temporal prediction mechanism **operating through entrainment**. We argue that **this view requires introducing the notion of a flexible (e.g. aperiodic) top-down phase-reset** of neuronal oscillations into the stimulus-**driven** model. **Concerning** the putative sources of top-down

modulation, we suggest that in the context of temporally structured auditory sequences, the motor system constitutes a plausible candidate to generate flexible (periodic and aperiodic) temporal predictive signals and to influence perception in a top-down manner [9–13] (Box 3). We also consider other sources of temporal predictions related to distinct cognitive processes [10,14–16]. Finally, focusing on speech as an informationally complex but predictable signal (containing quasi-periodic and aperiodic regularities), we exemplify how the framework we advance improves the explanatory power of classical entrainment models and generates novel testable hypotheses.

The classical entrainment model and temporal predictions

Entrainment aligns behavior with periodic events

Temporal predictions have been studied in paradigms where predictions are set-up in a bottom-up, stimulus-driven manner by periodic stimulation. Typically, auditory targets, are detected more easily when presented on-time in an isochronous sequences than when presented early or late, or preceded by a temporally random tone sequence [17]. A by-now classical view, the ‘**Dynamic Attending Theory**’ (DAT; [2,18]), proposed that attention is directed in time through the entrainment of neuronal oscillations to such periodic stimulation (Box 1). Oscillatory entrainment (as measured using electrophysiological recording) refers to the phase alignment and frequency adaptation of endogenous neuronal oscillators, to a periodic stimulation (Fig. 1 A2, Key Figure). In the DAT view, entrainment narrows the time-based attentional focus and optimizes perception [18]. This theory has strongly influenced visual, auditory, attention, music, and speech processing research [19]. However, while the DAT –and more generally oscillatory entrainment theories– provide an efficient and plausible neural mechanism to serve periodic temporal predictions, it cannot account for the brain’s capacity to generate –and benefit from– temporal predictions inferred from aperiodic patterns.

Aperiodic temporal predictions: aperiodic but predictable streams

The notion of temporal predictions is often confounded with the idea of entrainment to periodic sensory inputs. The latter mechanism, however, cannot account for temporal predictions inferred from heterochronous streams of events [8,20], symbolic cues (‘memory-based’ predictions, e.g. a yellow traffic light that indicates a switch to red in a few seconds), or hazard functions (‘probability-based’ predictions, e.g. the increasing conditional probability over time that an event

will occur given that it has not already occurred) [21,22]. For example, aperiodic temporal predictions occur in language (cf. last section), or in music, where many musical traditions employ non-isochronous (aperiodic) meter, which builds up temporal expectations and can be embodied in dance [6]. Comparing the ability of listeners to extract temporal regularities from periodic as well as aperiodic but –implicitly– predictable sound streams, a recent study [8] showed that performance is equally enhanced for predictable conditions (whether periodic or not) as compared to unpredictable ones. Another study [7] compared the neural responses to periodic and aperiodic predictions and demonstrated that periodic and aperiodic temporal predictions induce similar phase alignment of low-frequency activity prior to an expected target (see also: [23]). These observations contrast with entrainment models, which hypothesize that reducing stimulus periodicity should result in reduced phase-alignment. Importantly, these findings suggest that a single neural substrate could account for both periodic and aperiodic predictions at the sensory level (for criticism see: [24]).

The ‘**rhythmic attending mode**’ proposed by the DAT (where attention is directed in time through the entrainment of neuronal oscillations; Fig. 1 A2) can be extended by multiple oscillators being hierarchically organized (nested), and thus indirectly entrained to complex, multi-scale, rhythms [18]. Furthermore, under sustained vigilance task demands, the DAT proposes an ‘**analytic attending mode**’. In this mode, in the absence of a periodic stimulation, low frequencies are suppressed and high frequency activity subserves continuous processing by keeping the system in a high-excitability state [17]. Such models, however, cannot provide a mechanistic solution with respect to aperiodic temporal predictions. It has been proposed that aperiodic predictions rely on memory based ‘interval-timing traces’, to which new intervals are compared [7], an idea compatible with intrinsic models of timing [25]. Such a mechanism does not require periodicity but instead relies on anticipatory processes based on the learning of temporal contingencies. At the neurophysiological level, this has been associated with ‘**ramping-based models**’ (for review [25]) where the build up of expectations is reflected in linearly increasing neuronal firing rates (ramping or ‘**Climbing Neuronal Activity**’, CNA). In ramping-based models, recurrent excitatory connections within neuronal networks integrate the spiking information to estimate interval duration. Although involved in interval timing, ramping activity seems to encode stimulus probability rather than absolute time [26]. However, because these paradigms typically require a behavioral response, it is difficult to exclude the possibility that ramping activity reflects response

1 preparation, or time-dependent decision-making processes.

2 To summarize, temporal predictions are classically explained by oscillatory entrainment to periodic
3 sensory inputs. The facilitating effects of aperiodic predictions, however, cannot be accounted for
4 by entrainment, raising questions about the neural substrate of periodic and aperiodic predictions.

5 In the following, we outline an alternative approach to reconcile the findings and clarify the
6 connection between neuronal oscillations and predictive processing.

7 *Criticisms and refinements: the entrainment hypothesis revisited*

8 Whether distinct neuronal mechanisms exist for mediating periodic and aperiodic temporal
9 predictions, and whether the entrainment of low-frequency (<10 Hz) oscillations plays a **functional**
10 **role** for temporal predictions remains a matter of active debate (Box 2). One criticism about
11 attributing a function to the entrainment of neuronal oscillations is that correlation does not entail
12 causation (or specificity). That periodic auditory stimulation (as featured in speech or music, see
13 [4]) invariably entrains low-frequency neural oscillations does not imply that neural oscillations
14 play a functional role in temporal predictions.

15 We propose that neural oscillations primarily constitute an intrinsic processing constraint rather
16 than a dedicated temporal prediction mechanism operating through entrainment (Box 2). In this
17 perspective, the entrainment model (Fig. 1 A) can be refined to account for empirical observations
18 involving periodic and aperiodic predictions. The ‘constraint view’ extends the stimulus-driven
19 model by integrating the temporally flexible, internally-driven top-down alignment (**top-down**
20 **phase reset**) of neuronal oscillations to anticipated events. It assumes that neuronal oscillations do
21 not constitute a temporal prediction mechanism by itself, but are part of the cortical architecture
22 and support a more generic, canonical function, such as the message-passing of information
23 throughout the cortical hierarchy [27,28]. As a consequence, neuronal oscillations reflect
24 processing time constants, i.e. physiological (**intrinsic**) constraints due to the oscillatory
25 excitability cycles of neuronal ensembles. The preferred oscillatory frequency of these ensembles
26 determines optimal temporal frames for processing. Importantly, depending on both the networks
27 underpinning a cognitive process and their inter-connectivity and dynamics, specific temporal
28 constraints emerge [29–31]. The processing constraint view, contrasting with non-oscillatory
29 models [25,26], also accounts for empirical observations suggesting that perception is a discrete –

1 rather than continuous— process [32]. For example, auditory temporal processing is optimal within
2 certain time windows in the delta- and theta-ranges [33–35], which reflects endogenous brain
3 rhythms of auditory cortex [36–38]. Temporal constraints are also reflected in our ability to
4 understand time-compressed speech, which breaks down at compression rates exceeding the upper
5 limit of the theta range [39]. Further research will elucidate whether and under what conditions
6 plasticity can overcome these constraints.

7 Temporal predictions (periodic, aperiodic) operate upon endogenous constraints by predictively
8 aligning neuronal excitability in time to facilitate the processing of anticipated events (Fig. 1 B).
9 Top-down influences correspond to an anticipatory phase-reset (originating from higher-level
10 processes; not directly driven by low-level stimulus features) of ongoing oscillations in those
11 neuronal subpopulations involved in the processing of the expected event (e.g. beat or syllable)
12 [40]. While distinct neuronal mechanisms have been assumed for periodic (i.e., oscillatory
13 entrainment) and aperiodic (e.g., memory-based mechanisms) temporal predictions (for review:
14 [21]), we propose that entrainment of neuronal oscillations is one possible manifestation of a
15 common temporal prediction mechanism, in which stimulus-driven and top-down phase-resets co-
16 occur synchronously (Fig. 1 B). While it may not be possible to dissociate between stimulus-driven
17 and top-down influences during periodic stimulation, the evidence of phase-alignment in aperiodic
18 or contextual situations [7,40] argues in favor of the existence of internally guided, top-down
19 predictive phase-resets.

20 In the following, we discuss the evidence for top-down effects originating in different brain areas
21 and their role in (a)periodic temporal predictions (in the form of top-down phase resets).

22 Top-down sources of temporal predictions

23 By enabling the efficient allocation of processing resources, predicting upcoming inputs reduces
24 sensory uncertainty, thereby enhancing the processing of noisy (weak or ambiguous) inputs. To
25 reduce both external and internal noise, the brain can arguably exploit any available source of top-
26 down priors. Consequently, all neural systems that contribute to precise, time-related computations
27 might inform sensory processing in a top-down manner, without being selectively dedicated to this
28 function [25]. The next section describes the neural sources and mechanisms involved in reducing
29 sensory uncertainty in the time-domain.

The motor system's expertise in temporal predictions

Auditory perception is carried out within functionally dissociable pathways, the ventral and dorsal streams [41,42], comparable to visual perception [43]. Following predictive processing theories [44], the dorsal pathway is related to the processing of spatial and temporal features and establishes predictions that pertain to 'how' and 'when' something will happen.

The capacity of the dorsal stream for sequence processing has been associated with the timing capabilities of the motor system [45]. Precise temporal anticipation at the time-scale of tens to hundreds of milliseconds is critical, as a large number of phenomena pertaining to perception and action (i.e., speech and music perception and production, movements, etc.) occur at this scale. Several studies have shown that the motor system is involved, as part of a cortico-striatal network, in the processing of events and sequences at these time-scales (~above 300 ms) [46,47]. This is not surprising, given the expertise of this system in monitoring the sensory feedback resulting from motor outputs. The motor system is not only involved in motor-timing, however, but also recruited during rhythm perception in passive listening tasks, even when attention is directed away from the auditory stream [48–50]. These effects directly speak to the universal inclination to automatically synchronize our movements to external rhythms [47]. Additionally, evidence for the role of the motor system in timing is that the predictive alignment of neuronal excitability depends on sensory-motor expertise [51] and improves with periodic-motor priming (vocally) or audio-motor training [52].

It is therefore plausible that predictive timing in perception and action rely on similar systems, computations, and neurophysiological mechanisms [45,53]. On this view, temporal predictions in the auditory domain correspond to a covert form of **active sensing** [12,54]. In other words, the **efferent motor signals** that are generated when producing audible actions are also generated during the passive perception of temporally structured auditory streams [47,48,50,55,56]. These signals propagate downward toward sensory systems to predictively phase-reset and align ongoing oscillations in auditory cortex with upcoming events [11,15]. By comparing simulated and actual sensory outcomes, prediction error responses can be computed and used to learn, correct, and improve temporal predictions. At the neurophysiological level, temporal predictions might be carried by beta-band (~20 Hz) motor related signals, that are also related to the representation of temporal information [11,49,57–59] (Box 3).

1 Importantly, the motor system relies on a flexible internal repertoire of actions (i.e. we can perform
2 actions with diverse temporal dynamics) to emulate the temporal trajectory of upcoming inputs.
3 Because of this flexibility, this model does not require distinct mechanisms for periodic versus
4 aperiodic temporal predictions. While we assume that the specific role of motor-driven efferent
5 signals lies in aligning the phase of ongoing oscillations in sensory regions, the operational
6 mechanism arguably involves many other structures. For instance, it has been proposed that the
7 specific computations underlying time estimation are carried out by subcortical structures, probably
8 the basal ganglia or the cerebellum, depending on the specifics of the duration to be estimated, with
9 the putamen involved in relative or beat-based duration estimation and the cerebellum in absolute
10 or discrete duration estimation [60–62]. The inferior parietal cortex [63,64] is also possibly
11 involved at the interface between motor-driven internal predictions and sensory processing, i.e.
12 redirecting the modulatory efferent signals according to stimulus- and task-relevance.

13 Altogether, the experimental data suggest that the motor system is automatically recruited to track
14 temporal regularities (whether periodic or aperiodic) and proactively enhance the processing of
15 upcoming events. Whether the motor system’s recruitment is actually necessary for perception or
16 just useful in noisy or adverse listening condition remains debated. Moreover, whether temporal
17 predictions exploit efferent motor signals [65], and the underlying pathways remains to be
18 determined [12].

19 *Alternative sources of temporal predictions*

20 The motor system, even in a broad sense, is unlikely to be the sole system that contributes to the
21 predictive facilitation of perception in the time domain. For instance, recent findings in non-human
22 primates demonstrate the involvement of the pulvinar in the top-down phase reset of neuronal
23 oscillations in the primary auditory cortex [40]. Importantly, these findings provide evidence for
24 phase-alignment to statistical regularities (pattern repetition) in the absence of relevant periodicity
25 in the stimulation.

26 Humans exploit other forms of aperiodic temporal predictions e.g. symbolic cues that activate
27 associated memories and infer target timing [21]. Such types of predictions –based on working or
28 long-term memory– arguably involve the hippocampus [66]. Whether these systems predictively
29 shape perception through top-down phase reset of neuronal oscillations has, to our knowledge, not
30 been systematically investigated. Support for the notion of top-down phase reset comes from

research on symbolic cues used in higher-level language processing (cf. following section) and selective attention to certain points in time [21]. Top-down expectations, manipulated using predictive cues or stimulus probability of occurrence, enhance performance and predictively reset intrinsic sensory rhythms - such as alpha and theta oscillations in vision [67–69] and delta oscillations in audition [23]. In crowded auditory settings (e.g. cocktail party experiments), selective attention facilitates temporal tracking [70,71] by aligning excitability with stimuli in the attended stream. Tracking the speech of one particular talker enhances the alignment between the stimulus and low-frequency oscillations in auditory cortex and higher processing areas [71]. Similarly, prior knowledge of sound patterns that are inserted within a sound sequence, can be used to attend selectively and align oscillatory activity to those patterns [40,72].

Additional brain regions not belonging to the core motor system are involved in cueing paradigms. In these settings, temporal predictions are typically reflected in anticipatory electrophysiological components [25,73]. Such signals have been observed in various regions, including the anterior cingulate cortex, premotor cortex, posterior parietal cortex, supplementary motor area (SMA), and pre-SMA [26,74], all of which arguably contribute to proactive simulation processes. Whether these electrophysiological signals reflect anticipatory computations locally, or whether they actually propagate top-down to subserve the predictive modulation of sensory excitability remains to be determined (Fig. 1 B).

A/periodic predictions - Speech as relevant case

Temporal processing is typically studied using highly simplified stimuli (e.g. tone sequences). Although useful, this does not allow us to fully capture the essence of predictive processes, namely to enhance the analysis of complex, ecological signals. Speech constitutes an informationally rich signal from which temporal regularities at many time-scales can be used to facilitate processing. It provides a theoretical challenge and a valuable experimental assay to investigate the substrates and mechanisms underlying predictive processing.

The entrainment view on speech processing

Despite controversy about the extent of rhythmic structure in the speech signal [75], most languages exhibit remarkably similar temporal modulations at around 4-8 Hz reflecting quasi-periodic fluctuations of the amplitude envelope and implicating the syllabic scale [4,76]. Current

1 data suggest that entrainment of intrinsic neuronal oscillations (theta-band, 4-8 Hz) in auditory
2 cortex [36,38,77–79] aligns high neural excitability phases in the output layers of auditory cortex
3 [77]. In this framework, entrainment to acoustic landmarks (sharp amplitude modulations; [80])
4 sets up temporal frames that allow the brain to segment the signal at the syllabic scale [77].
5 Coupling of theta and (low, 25-35 Hz) gamma rhythms [81,82] reflects the hierarchical
6 organization between syllabic and phonemic cues and allows for simultaneously segmenting and
7 extracting the syllabic and phonemic information [77]. Conclusive evidence that the observed
8 activity reflects oscillatory entrainment rather than iterated evoked responses or anticipatory
9 components remains sparse (Box 1).

10 *Temporal constraints in speech processing*

11 Recent experimental observations set oscillatory entrainment in a different light, intimating that a
12 new interpretative framework is needed to account for these phenomena. For example, that theta-
13 band entrainment occurs with natural as well as with time-reversed, unintelligible speech [83]
14 questions the initially assumed functional role of theta oscillations in comprehension, and suggests
15 an involvement at lower processing levels. On the other hand, although not sufficient, theta
16 entrainment is likely a necessary precondition to ensure speech comprehension [80]. Using
17 (unintelligible) compressed speech, studies have shown that introducing periods of silence (80 ms)
18 between periods (40 ms) of compressed speech restores comprehension [35]. This suggests that
19 speech comprehension is limited by the amount of time needed to decode the information into
20 exploitable internal representations [84].

21 Another criticism of a stimulus-driven entrainment account for speech is that phase alignment to
22 acoustic landmarks [80] needs to be continuously adjusted, because of the quasi- (but not strictly)
23 periodic nature of speech. Thus, the observed speech tracking requires a more flexible mechanism
24 [33,85].

25 These observations are compatible with the view that intrinsic rhythms impose temporal constraints
26 on sensory processing [84]. This idea predicts that to be optimally processed, connected sound
27 sequences (e.g. speech, music) should be provided in temporal chunks of adequate length to match
28 hierarchical oscillatory temporal scales [77,78]. Importantly, although oscillatory constraints may
29 have a limited impact when stimuli are easy to process, they are relevant in noisy or adverse
30 listening conditions, where top-down processes are recruited to operate upon these constraints to

1 optimize sensory processing.

2 *Top-down phase reset in speech processing*

3 In light of the syntactic and semantic variability of language, the timing of high-level linguistic
4 information is typically more variable than that of lower-level input features [86]. Although
5 syntactic/semantic information is not necessarily provided in a periodic manner, it allows
6 generating probabilistic predictions of upcoming speech [87,88] and thus constitutes an aperiodic,
7 symbolic source of temporal predictions. The capacity of syntactic-semantic contexts to permit
8 temporal predictions and facilitate processing has been shown in early reaction time [89] or eye-
9 tracking studies [90]. Linguistic corpora-based computational models showed that syntactic
10 information, e.g. whether the last constituent was a noun or verb phrase, predicts pause timing in
11 continuous speech [5]. That syntactic predictability crucially relies on timing abilities, is supported
12 by basal ganglia patients deficits in using syntactic predictions in a temporally irregular context
13 [91].

14 Accordingly, several studies suggest that during speech perception, motor and higher-linguistic
15 processing areas predictively reset and align low-frequency activity in the auditory cortex
16 [10,15,79,92]. Optimal audio-motor coupling is observed for stimuli presented within the range of
17 the natural syllabic rate (i.e., ~ 4 Hz [92]) and during speech perception [10,15,79]. Comparing
18 intelligible versus backward speech, these studies further show that speech tracking and
19 comprehension are optimized by feedback from higher-level linguistic processes [15,16,70]. These
20 top-down predictions arguably enhance the precision of speech processing through anticipatory
21 top-down phase-reset of neuronal oscillations, as reflected in phase-phase and phase-amplitude
22 coupling measures [10,93]. Similarly, cross-modal enhancement of speech perception by lip-
23 reading is possibly mediated by higher-order frontal/motor regions through low-frequency phase
24 alignment [13,93,94]. These findings suggest that predictions from multiple levels and networks
25 can optimize neural entrainment to speech and intelligibility [10].

26 Despite these advances, whether linguistic predictions feedback to sensory processing levels
27 remains unclear [95]. Furthermore, the origins of top-down linguistic predictions –whether at the
28 phonological [14,96,97], lexical [96] and/or sentence level [98]– are complicated and poorly
29 understood. What roles the motor cortex plays in speech perception is also actively debated [99].
30 In addition to generating temporal predictions, speech motor areas presumably represent

1 phonological information [100]. To capture the essence of the motor contributions in speech
2 comprehension, and in line with the constraint view, we argue that it is necessary to consider audio-
3 motor coupling has a key mechanism [101].

4 In summary, predictions based on the motor system or higher-level language processing seem to be
5 effectively used to facilitate perception and enhance speech tracking. Further research is required
6 to elucidate the mechanisms and nature of the top-down signals provided by frontal, motor and/or
7 other areas and how these align temporal constraints at the sensory level.

8 Concluding Remarks and Future Directions

9 We propose a parsimonious framework for auditory temporal predictions, including for predictive
10 processing of speech. We suggest a neuronal implementation that simultaneously makes possible
11 bottom-up (stimulus-driven) and top-down (motor-driven, language-driven) phase-reset of low-
12 frequency oscillations in auditory cortex. On the proposed view, neuronal oscillations do not a
13 priori subserve *specific* functions but rather constitute an intrinsic temporal constraint. Top-down
14 phase-reset signals are generated to predictively align these internal temporal frames (excitability
15 cycles) and improve stimulus processing. This hypothesis, meant to synthesize current debates and
16 data on temporal predictions from research in neuroscience and psycholinguistics, is of course far
17 from comprehensive and requires development to evaluate the details of the operations
18 (Outstanding Questions).

Box 1 Entrainment of neuronal oscillations

Neuronal oscillations are ubiquitous in the brain of vertebrates and are seen even in the absence of external stimulation. Brain rhythms most likely emerge from neurons acting as self-sustained oscillators with a natural frequency [102,103] and thus can act as pacemakers. Spontaneous oscillations have been described in several brain areas, including delta (1-4 Hz), theta (4-10 Hz) and gamma (30-50 Hz) oscillations in primary auditory cortex [78]. Natural frequencies arguably arise from subthreshold oscillations in the membrane potential of neurons, or short-term depression and facilitation at the synaptic level (which can be different for synapses of the same presynaptic cell, allowing selective network communication) [103,104]. Importantly, band-limited oscillatory dynamics pre-exist in auditory cortical regions [36–38] and **resonate** after the end of an auditory rhythmic stimulation [52,105–107] supporting the notion of intrinsic oscillators.

Building upon the successful application of oscillatory entrainment models to the study of circadian rhythms [108,109], subsequent research extended such models to investigate a putative role of neuronal oscillations in temporal attention [2]. Entrainment typically denotes that a quasi-periodic external stimulation aligns the phase of slow (~1-10 Hz) endogenous neuronal oscillations in the same frequency range (as measured with magneto- or electro-physiological recordings) and often modulates behavior accordingly [17,110]. There exists a wealth of evidence that brain rhythms coincide with the rate (~1-10 Hz) of certain cognitive domains (e.g. speech, music; [4]), and preferred temporal rates of sensory processing [111]. Thus, it is often assumed that oscillatory entrainment plays an instrumental role in temporal processing [17,77], and sensory selection [3,78,112].

These assumptions need careful methodological consideration. First, the use of sinusoidal transformations (e.g. Fourier and wavelet transforms) to analyse neural time-series results in displaying apparently –but possibly spurious– oscillatory features, thereby raising potential interpretative issues [113]. In addition, in the context of periodic stimulation, it is challenging to distinguish oscillatory entrainment from repetitive, event-related potentials [114,115], or endogenous anticipatory activity (e.g. Contingent Negative Variation, CNV; [73,116]). To disentangle these processes, it is important to develop novel experimental paradigms isolating exogenously driven from endogenously driven neural effects (see [7,11,19]).

Box 2 Neuronal functions and processing constraints

One striking feature of current neuroscience research is that the operationalization of cognitive functions (e.g. consciousness, memory) coincides with the identification of dedicated oscillatory processes. Thus it has been implicitly assumed these processes are causally linked – and therefore a functional relevance has been attributed to neural oscillations. The term ‘function’, however, is controversial and usually undefined in cognitive neuroscience. Here we favor a ‘causal role theory’ of physiological function, wherein a process is called a function when it causally contributes to the behavior of a system [117]. We distinguish between neurophysiological phenomena that underlie generic neuronal processes versus phenomena that causally subserve specific cognitive processes. The first are necessary but not involved in one specific function. They ‘constrain’ cognitive processes by being part of the neurophysiological architecture. In contrast, the latter are necessary for a specific cognitive function.

Even without compelling evidence, claims have been advanced that oscillations are functionally specific to various cognitive processes, e.g. [118]. Other accounts suggest, however, that oscillatory processes support a more generic, canonical function: the message-passing of information throughout the cortical hierarchy [27,28]. The canonical architecture imposes ‘cyclic temporal constraints’ on cognitive processes, as the frequency of oscillations of a neuronal population determines the excitability fluctuations of these neurons, thereby periodically imposing alternating phases of high and low excitability [78]. Because cognitive processes imply the transmission of information between neuronal populations, they entail specific spectral signatures possibly reflecting processing constraints.

The constraint interpretation accounts for many observations, including empirical evidence for discrete perception [32,33,35], and should perhaps be preferred to functional interpretations, as long as it is not possible to provide evidence otherwise. Crucially, [as we propose here](#), it accounts for the functional effectiveness of predictive top-down resets on sensory processing for both periodic and aperiodic temporal predictions.

Box 3 Beta-band oscillations involved in top-down predictions

Beta-band activity is typically evidenced in sensory-motor areas during temporal tracking as well as during continuous speech processing [11,49,57,59,119,120]. Recent evidence suggested that beta-band activity in motor regions proactively tracks the timing of upcoming events and modulates low-level auditory processes to facilitate behavioral responses [11,49,57] (Fig. I, during selective attention to target tones, modulated at 1.5 Hz, temporal predictions are encoded in delta-beta coupled oscillations functionally directed toward auditory regions to modulate the 3 Hz auditory input, adapted from [11]).

Beta-band signals are also involved in top-down predictions of higher level linguistic features, such as semantic and syntactic predictions [121,122]. Therefore, it has been suggested that top-down signals carried by beta-band oscillations indicate more than ‘mere’ temporal predictions but communicate accurate information about the content of the expected events, as suggested by their role in lexical/semantic predictions of upcoming words but not of the syntactic category (for review, see [88]).

However, the functional relevance and specificity of beta-band oscillations for predictive processes remains to be clarified. One plausible account for current empirical findings is that beta-band activity is more generically involved in feedback communication between brain areas [28]. In the ‘predictive routing’ account, descending beta-band signals predictively pre-activate neuronal population that are relevant for the processing of expected inputs [123]. Consistent with this view, recordings in the macaque and human early sensory cortices support the involvement of beta-band signals originating in deep cortical layers in the top-down propagation of information [81,124–126].

In sum, although the detailed neural mechanisms remain to be elucidated, the data supports the notion that beta-band signals predictively modulate sensory processing. Moreover, while the nature of the predictive information seems to depend on the source-region generating beta oscillations, temporal predictions are specifically associated with motor-related beta activity.

1 Outstanding Questions

- 2 • If intrinsic neuronal oscillations constitute generic constraints that pre-exist
3 (ontogenetically or phylogenetically), can these oscillations be experimentally evidenced
4 prior to the emergence of specific functions (e.g. language or sequence processing), for
5 example in non-verbal infants or primates?
- 6 • Is the efficiency of predictive neural alignment and ensuing behavioral improvement solely
7 conditioned by sensorimotor training and expertise [51]? Alternatively, could other types
8 of plasticity, such as repeated exposure to these sequences or sensory deprivation [127]
9 result in adapting oscillatory constraints at the sensory level?
- 10 • Are ramping components (e.g. CNA) a mere signature of anticipatory activity or do they
11 play a causal role (akin to phase resets) in predictively shaping sensory processes in a top-
12 down manner? In the latter case, what would be the nature (modulatory, driving) of the
13 underlying mechanism?
- 14 • In line with the notion of intrinsic timing models, do all neural systems that perform precise,
15 time-related computations (e.g. motor, attentional or memory systems), use similar (or
16 shared) mechanisms to prospectively influence perceptual processes?
- 17 • Given that hierarchically structured temporal signals (e.g. speech and music) embed
18 multiple, nested levels of temporal regularities, is the motor system involved in proactively
19 tracking temporal regularities at all (e.g. syllabic, prosodic or phrasal) or only at specific
20 levels?

21 Glossary

22 **Active sensing:** denotes the proactive contribution of sensorimotor processing to perception. One
23 implementation relies on top-down predictions based on internal copies of movement commands
24 (see also corollary discharge);

25 **Analytic attending mode:** in sustained vigilance settings, high frequency activity maintains a
26 continuous high-excitability state of the system, in order to support attention;

27 **Climbing neuronal activity:** ramping anticipatory neuronal activity that increases until –and is

resolved after— an expected time point;

Constraint: in reference to neural processing, denotes aspects of the neuronal architecture that affect neuronal functions but are not specific or instrumental to a certain function;

Dynamic Attending Theory: describes how entrainment of neuronal oscillations to a periodic stimulation directs attention in time;

Efferent motor signals: signals generated by the motor system to propagate down to peripheral systems to generate overt —but also possibly covert— movements.

Entrainment: the process through which two or more self-sustained oscillators become coupled (Box 2);

Functional role: central but controversial and not well-defined concept in neuroscience; here, a ‘causal role theory’ of function is favored, where a process is called a function if it causally and specifically contributes to the functional capacity of a system. In contrast, ‘selectionist theories’ define the function of a process with regard to its contribution to natural selection;

Hazard functions: describe the probability of occurrence of forthcoming events;

Modulate: processes that change the responsiveness and effectiveness of driven neuronal responses [128];

Phase alignment: neuronal oscillatory excitability phases co-occur with energy phases of a periodic stimulation;

Parsimony (see also Occam’s razor and *lex parsimoniae*): the principle that among competing hypotheses, the one underlying the fewest assumptions should be preferred.

Periodic: successive events are separated by a constant duration;

Ramping-based models: monotonic changes in firing rate encode time until a threshold is met;

Resonate: resonance is a passive phenomenon where neuronal responses reflect the stimulation frequency. This is generally distinguished from oscillatory phenomena, where neurons oscillate at a preferred frequency in the absence of a stimulation and can entrain to an external stimulation;

Rhythmic: in music (and language) terminology acoustics that contain a regular pattern with respect to timing. Although periodic patterns are always rhythmic (and rhythmicity and periodicity are often used synonymously) the reversal is not true; [129]; Oscillatory brain activity is called rhythmic (Box 1), whereas most measures analyze periodicity.

Rhythmic attending mode: entrainment of neuronal oscillations to a periodic stimulation directs attention in time;

Symbolic cues: cues that activate associated memories about the target timing;

Temporal regularities: a statistical rule that can be extracted to predict a temporal pattern;

Tracking: the neural sensory response profile reflects the energy fluctuations in the acoustic (e.g. the envelope of speech or the stimulation rate of sounds);

Top-down phase-reset: endogenous, non stimulus-driven process that aligns the phase of neuronal oscillations with an expected event to facilitate its processing;

Figure legends

Figure 1. Comparison between standard and top-down entrainment models. Intrinsic oscillations impose periodic alternations of low (green) and high (red) excitability. The instantaneous phase of ongoing oscillations thus directly impacts neuronal responsiveness, information processing (colored circles) and behavioral outcome (middle panels, the performance outcome reflects the weighted average of excitability phases at stimuli onsets). Typically, stimuli (black rectangle) induce a bottom-up phase-reset (dashed lines; note however, that exogenous reset effects being similar for both models, are not represented for clarity). Sine waves depict the behavior of a local, intrinsic oscillator that resonates at a certain frequency (e.g. delta-theta) and constrains (i.e. biases [130]) sensory processing. Four scenarios of stimulation are presented (rows): 1- aperiodic random (non-predictable), 2- periodic predictable (at a rate compatible with the intrinsic frequency of the neuronal oscillators), 3- aperiodic but predictable (here, linearly accelerating), and 4- stimulus forewarned by a symbolic cue ('memory-based'; indicated by hierarchical linguistic tree icon). **(a) Entrainment model.** Neuronal oscillations reorganize reactively to stimulation, and are thus directly organized according to the temporal structure of the sensory sequences. Only in the case of a periodic sequence can neuronal oscillations be optimally aligned and maximize performance. **(b) Top-down reset model.** In the case of temporally predictable events (rows 2-4), top-down predictive signals (black arrows) phase-reset sensory neuronal oscillations prior to stimulus occurrence, which results in optimized performance. Climbing neuronal activity (CNA) might indicate top-down modulation of sensory processing (row 4) **(c) Brain areas** that can contribute to exert predictive, top-down control of sensory processing.

Figure I Motor predictions mediated by delta-beta coupled oscillations

1 *Outstanding Questions*

- 2 • If intrinsic neuronal oscillations constitute generic constraints that pre-exist
3 (ontogenetically or phylogenetically), can these oscillations be experimentally evidenced
4 prior to the emergence of [specific functions \(e.g. language or sequence processing\)](#), for
5 [example](#) in non-verbal infants or primates?

- 6 • Is [the efficiency of predictive neural alignment and ensuing](#) behavioral improvement solely
7 conditioned by sensorimotor training and expertise [\[51\]](#)? Alternatively, could other types
8 of plasticity, such as repeated exposure to these sequences or sensory deprivation [\[127\]](#)
9 result in adapting oscillatory constraints at the sensory level?

- 10 • Are [ramping](#) components ([e.g. CNA](#)) a mere signature of anticipatory activity or do they
11 play a causal role (akin to phase resets) in predictively shaping sensory processes in a top-
12 down manner? In the latter case, what would be the nature (modulatory, driving) of the
13 underlying mechanism?

- 14 • [In line with the notion of intrinsic timing models](#), do all [neural systems that perform precise,](#)
15 [time-related computations](#) (e.g. motor, attentional or memory systems), use similar (or
16 shared) mechanisms to prospectively influence perceptual processes?

- 17 • [Given that hierarchically structured temporal signals \(e.g. speech and music\) embed](#)
18 [multiple, nested levels of temporal regularities](#), is the motor system involved in proactively
19 tracking temporal regularities at all (e.g. syllabic, prosodic or phrasal) or only at specific
20 levels?

21

(c) Sources of Temporal Predictions
