ABSTRACT. The safe storage of flammable gases, such as acetylene, is essential for current industrial purposes. However, the narrow pressure and temperature range required for the industrial use of pure acetylene ($100 < P < 200$ kPa at 298 K) and its explosive behaviour at higher pressures make its storage and release challenging. Flexible metal–organic frameworks (MOFs) that exhibit a gated adsorption/desorption behaviour — in which guest uptake/release occur above threshold pressures, usually accompanied by framework deformations — have

shown promise as storage adsorbents. Herein, the pressures for gas uptake and release of a series of zinc-based mixed-ligand catenated MOFs were controlled by functionalizing the two ligands as well as changing their ratio. This affects the deformation energy of the framework, which in turn controls the gated behaviour. The materials offer good performances for acetylene storage with a usable capacity of ~ 90 v/v (77 % of the overall amount) at 298 K and under a practical pressure range (100–150 kPa).

The development of new technologies for efficient gas storage at ambient pressure can improve safety and provide new possibilities for gas cylinder design. The usable gas capacity, which differs from the maximum quantity adsorbed, under mild pressure and temperature conditions is another concern for researchers. In contrast to gases such as carbon dioxide, methane, oxygen, and nitrogen, which have wider compression pressure tolerances, pure acetylene gas is challenging to handle and safely store due to its explosive behaviour when compressed over 200 kPa at room temperature. Consequently, in the last century, cylinders have been filled with acetylene dissolved at high pressure (P > 1500 kPa) in a solvent such as acetone.[1-3] However, such acetylene commercial set-up could contaminate the acetylene gas. When cylinders are filled with pure acetylene gas at 200 kPa (safe pressure), it only allows the release of 50 % of its total capacity at 100 kPa (limit pressure for the gas to flow spontaneously), keeping 50 % unused, which is not economically useful and potentially dangerous. The creation of porous materials capable of delivering large quantities of pure acetylene in a highly narrow pressure range (100–150 kPa) at room temperature is therefore essential.[4]

As a potential solution, porous materials, particularly metal-organic frameworks (MOFs) or porous coordination polymers (PCPs), possess inherent voids that allow the storage and delivery

of large amounts of gases.[5-8] In contrast to rigid materials showing a Langmuir type I isotherm, flexible MOFs, also called soft porous crystals (SPCs), possess both ordered network and structural transformability, resulting in a sigmoidal S-shape isotherm and higher usable storage capacity (USC) when the gate pressures are in the desired working pressure range (**Fig. 1**).[9-12]

The flexibility depends not only on the binding capacity and mobility of unit ligands and metal ions but also on other factors, including the deformation of the entire framework as a result of the guest molecules in the pores.[13-15] Strategies using ligand functionalisation have been developed to investigate the behaviour and properties of flexible MOFs.[16-21] Still, none of them focused on gas storage and especially sensitive gas, which mandates strict temperature and pressure conditions.[22-27]

Regarding acetylene storage, rigid and flexible MOFs have demonstrated high adsorption capacities at 298 K and 100 kPa. However, the desorption pressure does not match the acetylene storage requirements for safe handling described above. All the MOFs reported for their high acetylene capacities were recorded at a pressure of 100 kPa, which is below the ideal working pressure range.[28-32] Speculative values were also calculated for acetylene adsorption at high pressure (P > 3500 kPa), far above the explosion limit for acetylene.[32] Herein, we demonstrate the optimum pressure range for stable acetylene storage while maintaining high deliverable capacity.[33-36] To the best of our knowledge, acetylene sorption isotherms on MOFs at a pressure range between 100–150 kPa have not been reported so far.

We used a doubly catenated structure, i.e., interpenetrated or two-fold interlocked, as an SPC candidate; [$Zn_2(bdc)_2$(4,4'-bpy)] (bdc = 1,4-benzenedicarboxylic acid; 4,4'-bpy = 4,4´-bipyridine) (**Zn-CAT**), where the mutual dislocation of the two identical framework motifs can introduce acetylene, displaying a sigmoidal sorption isotherm. The gate-opening and -closing

pressures (P_{go} and P_{gc}) depend on the deformation energy to create space, attributed to the interaction between the two interpenetrating frameworks.[37,38] Therefore, the isotherm can be controlled by the steric and electronic properties of the organic linker (L) of the framework. At a certain temperature, *T*, the isotherm is a function of *P* and L as A_T = F(P, L) (**Fig. 1**). The introduction of different ratios of functionalised **bdc-X** linkers (**X** = **–NO$_2$** or **–NH$_2$**) allows the optimization of the sigmoidal sorption at temperature storage and 100 kPa release of acetylene. The strategy of deformation energy control, as devised for acetylene, is also applicable to CO_2, O_2, and CH_4 gases in which lower filling and release pressures are preferable for the safer use of the gas cylinder.

Results and Discussion

Synthesis and characterisation

A series of **Zn-CAT** derivatives composed of a mixture of **bdc** and a substituted **bdc-X** (**X** = **–NO$_2$** or **–NH$_2$**) ligands were synthesised with precise control of the **bdc**/**bdc-X** ratio (**Figs. 2a–c** and Supplementary **Fig. 1**).[37] The final linker ratio of these **[Zn$_2$(bdc)$_{2-a}$(bdc-X)$_a$(bpy)]** materials (with **a** varying from 0 to 2) was confirmed by ^{1}H NMR and showed almost no deviation from the linker ratio expected from the introduced mixture (**Fig. 2c** and Supplementary **Figs. 2–14**). The samples were designated according to **Zn-CAT-(X)$_n$**, that is, the functional moiety (**X** = **–NH$_2$**, **–NO$_2$**) and molar percent (***n*** = 0–100%) for clarity. All materials were thermally stable up to 623 K, as observed by thermogravimetric analysis (TGA) (Supplementary **Figs. 15–17**). The SEM images of the as-synthesised samples were then analysed and exhibited homogeneity of particle sizes in the micrometre range (Supplementary **Figs. 18–19**). Powder X-ray patterns (PXRD), infrared analysis (IR), UV-vis and crystal structures of the as-synthesised and activated samples confirmed the purity of all materials as well as their isostructural nature

(Supplementary **Figs. 20–26** and **Tables 1–2**). Interpenetrated **Zn-CAT** shows a dynamic transition from the closed (when the structure is completely evacuated from guests) to the open form (when a specific gas pressure or temperature is applied).[39] Thus, the gas sorption properties of the **Zn-CAT-(X)$_n$** series were investigated.

First, **Zn-CAT-(X)$_n$** samples were confirmed to behave as a solid solution; that is, the ligands were homogeneously distributed within the backbone structures (Supplementary **Fig. 27**).[40,41] The influence of the ratio of linker mixture on the P_{go}/P_{gc} pressures was determined from single gas-adsorption measurements performed at different temperatures and pressures (**Fig. 3** and Supplementary **Figs. 28–36**). Acetylene physisorption of pristine **Zn-CAT** at 273 K showed P_{go} = 44 kPa and P_{gc} = 19 kPa with an excess amount of 2.87 mol.mol^{-1} of acetylene adsorbed (**Fig. 3**).[39] When **Zn-CAT-(NH$_2$)$_n$** is used, a shift in P_{go} from 48 to 83 kPa was observed as n increased from 5 to 60% (**Fig. 3a**). In contrast, for **Zn-CAT-(NO$_2$)$_n$**, the gate-opening pressure shifted to a lower pressure when n increased from 5 to 100 % (from P_{go} = 31 kPa to P_{go} = 1 kPa) (**Fig. 3b)**. The plot of the gate-opening and -closing pressures as a function of the molar percentage of amino groups in **Zn-CAT-(NH$_2$)$_n$** suggests that P_{go} increases exponentially with the amount of **bdc-NH$_2$** incorporated (**Fig. 3c**). At a higher molar percentage (n > 60%) of **bdc-NH$_2$**, P_{go} was not observed below 100 kPa; however, the value can be extrapolated from the exponential fit of the lower molar percentage data points and later confirmed by high-pressure measurements (**Fig. 3** and Supplementary **Figs. 37–44**). This extrapolation is possible due to the exponential trend observed at a lower temperature (195 K), where all P_{go} values can be determined for high amino loading (Supplementary **Figs. 28–29**). Additionally, the nitro group exhibited a significant impact on the exponential decay of P_{go} as a function of n (**Fig. 3d**).

***In-situ* gas sorption studies**

The structure of **Zn-CAT**, **Zn-CAT-$(NH_2)_{100}$**, and **Zn-CAT-$(NO_2)_{100}$** were also characterized by *in situ* PXRD under various acetylene pressures at 195 K (Supplementary **Fig. 45**) to further investigate the effect of **bdc** substitution and phase transformations.

Increasing the gas pressure resulted in a transition from a close to open phase structure, which occurred at different pressures for the three samples. The gate-opening pressures, which correspond to the phase transition observed on the PXRD patterns, were observed at P_{go} = 0.04, 0.21, and 1.16 kPa for **Zn-CAT-$(NO_2)_{100}$**, **Zn-CAT**, and **Zn-CAT-$(NH_2)_{100}$**, respectively. The difference in the parent structure can explain this difference. Below P_{go}, the PXRD patterns of activated MOFs (closed form) for **Zn-CAT-$(NH_2)_{100}$** and **Zn-CAT-$(NO_2)_{100}$** show a decrease and increase in the volume of the cell, respectively, compared to pristine **Zn-CAT**, as seen from the shift of the 100 peak. These results were confirmed by the crystal structure obtained from X-ray diffraction experiments (Supplementary **Table 1–2**).[38] The cell volume of activated **Zn-CAT-$(NO_2)_{100}$** (715.9 $Å^3$) is higher than that of **Zn-CAT** (703.6 $Å^3$) and **Zn-CAT-$(NH_2)_{100}$** (701.9 $Å^3$), which can be attributed to i) the softer interaction of –**NO_2** groups with the metal nodes and ii) the steric hindrance of the –**NO_2** moiety, which further separates the aromatic part of the ligand. Therefore, the stabilisation of the structure through π–π interactions is reduced, as observed for pristine MOF. [42]

For **Zn-CAT-$(NH_2)_{100}$**, the higher pressure needed for the gate opening to occur is explained by the initially more contracted structure owing to interactions between –**NH_2** moieties and oxygen atoms from the metal paddlewheel.[38] Finally, all MOF structures are entirely open in the higher pressure range, and they display similar diffraction patterns (Supplementary **Figs.**

45d–f). Considering that the open and closed forms of each material are isostructural, the difference in the gate-opening pressure is attributed to the functionalised **bdc-X** linker.

Theoretical investigations of the gate-opening behaviour

To rationalise the effect of linker on the thermodynamics of the gate-opening process, we applied theoretical thermodynamic models to the adsorption isotherms of **Zn-CAT** and its derivatives (Supplementary information).[43,44] Researchers have previously shown that a simple two-phase model provides a good description of gate opening in interpenetrated frameworks. The gate opening is an adsorption-driven first-order phase transition from a nonporous phase to a microporous phase. Here, the "open phase" adsorption is described by a Langmuir-type fit of isotherms for all materials at 273 K. The free energy difference (ΔF) associated with the gate-opening process have been calculated based on the adsorption and desorption isotherms (see Supplementary Information for the equations). This value indicates that **Zn-CAT** exhibits a relatively small free energy difference (ΔF = 5.2 kJ/mol) between the two phases (here, all energies are reported per unit cell). This value is slightly larger, but of a similar order of magnitude, than those of other gate-opening materials, such as $[Cu(4,4'\text{-bpy})(dhbc)_2]H_2O$, which has a ΔF of approximately 4 kJ/mol).[21,45] The relatively small free energy difference between the two phases explains why the material readily opens upon adsorption of small guests.

However, the introduction of $-\mathbf{NO_2}$ and $-\mathbf{NH_2}$ substituents leads to a decrease in ΔF (see Supplementary **Table 3**). The impact of $-\mathbf{NH_2}$ was determined to be smaller than that of $-\mathbf{NO_2}$. The more pronounced decrease in ΔF of **Zn-CAT-$(NO_2)_{100}$** is attributed to the repulsive interaction of the $-\mathbf{NO_2}$ groups in the closed phase. Owing to the smaller energetic cost for gate opening, the opening is easier and occurs at lower gas pressures. This is particularly noticeable in the **Zn-CAT-$(NO_2)_{100}$** phase, where the free energy difference is almost zero, which implies that

the material is truly bistable. Minute amounts of adsorbate trigger the gate-opening transition. This effect was more complex when –**NH$_2$** groups are present. The introduction of –**NH$_2$** groups in **Zn-CAT** decreased ΔF but did not lead to a decrease in the gate-opening (and closing) pressure. The effect is smaller than that of the –**NO$_2$** groups because –**NH$_2$** is a less bulky substituent. Therefore, the change in ΔF is not the dominant factor, and the driving force is the evolution of affinity in the open phase, discussed in detail later in the paper.

These results suggest the possibility of purposefully controlling the gate-opening and closing pressure by introducing different ratios of functional groups. Additionally, the dependence of gate-opening and closing on the molar ratio of amino or nitro functional groups is not unique to acetylene. Still, it is also applicable to CO_2, O_2, and CH_4, demonstrating the method's versatility (Supplementary **Figs. 30–36**).

Notably, the total adsorbed capacity does not considerably change for all **Zn-CAT-(NH$_2$)$_n$** compared to that of pristine **Zn-CAT** for acetylene gas at 273 K (**Fig. 3c**). The total adsorption capacity at higher loading in the **Zn-CAT-(NH$_2$)$_n$** series was recorded at a lower temperature (T = 195 K), demonstrating that the total capacity did not decrease for all **Zn-CAT-(NH$_2$)$_n$** series (Supplementary **Fig. 28–29**). Conversely, the capacity decreases up to 15% for **Zn-CAT-(NO$_2$)$_{100}$** (from 2.73 mol.mol^{-1} to 2.32 mol.mol^{-1}). This difference is expected due to the bulkier nitro moiety (VDW surface area **bdc-NO$_2$** = 249.2 Å) compared to the amino moiety (VDW surface area **bdc-NH$_2$** = 223.3 Å).

To elucidate the origin of the counter-intuitive observation that the gate-opening pressure decreases after introducing a **–NO$_2$** group into **Zn-CAT** but increases after introducing an **–NH$_2$** group, quantum chemical calculations were carried out (see Supplementary Information for computational details). For clarity, only C_2H_2 adsorption onto pristine **Zn-CAT** and fully

substituted MOFs, that is, **Zn-CAT-(NH$_2$)$_{100}$** and **Zn-CAT-(NO$_2$)$_{100}$**, were considered. As shown in **Table 4** of the Supplementary Information, the binding energy (*BE*) of C_2H_2 with MOFs increased from **Zn-CAT-(NH$_2$)$_{100}$** (–9.3 kcal/mol) > **Zn-CAT** (–9.9 kcal/mol) > **Zn-CAT-(NO$_2$)$_{100}$** (–10.6 kcal/mol), where a more negative *BE* value indicates stronger C_2H_2 adsorption with increased energy stabilisation. The results suggest that C_2H_2 adsorption begins to occur at a higher pressure for **Zn-CAT-(NH$_2$)$_{100}$** but at lower pressure for **Zn-CAT-(NO$_2$)$_{100}$**, consistent with the experimental results.

The *BE* was decomposed into the interaction energy (E_{int}) between the MOF and C_2H_2 molecules and that of the adsorbed C_2H_2 molecules and the deformation energy (E_{def}) of the MOF structure by C_2H_2 adsorption. The E_{int} values were similar for C_2H_2 adsorption onto **Zn-CAT**, **Zn-CAT-(NH$_2$)$_{100}$**, and **Zn-CAT-(NO$_2$)$_{100}$**, which is reasonable because the adsorption positions of C_2H_2 in these MOFs are similar (Supplementary **Fig. 46**). However, E_{def} differs considerably and is of the same order as that of P_{go}. The larger E_{def} for **Zn-CAT-(NH$_2$)$_{100}$** indicates that the introduction of the **–NH$_2$** group into **Zn-CAT** results in a less flexible framework; thus, the gate-opening pressure increases. The less flexible framework occurs due to the hydrogen-bonding interactions of the **–NH$_2$** group with the neighbouring **bpy** and carboxylate ligands (Supplementary **Fig. 47a**). The hydrogen-bonding interaction between the **–NH$_2$** group and the **bpy** ligand weakened after C_2H_2 adsorption, confirmed by the increase in the **NH$_2$-bpy** distance (Supplementary **Fig. 47a-b**). For **Zn-CAT-(NO$_2$)$_{100}$**, the introduced **–NO$_2$** group results in a repulsive interaction with the carboxylate ligand (Supplementary **Fig. 47c**) in the guest-free structure. Consequently, the framework flexibility is increased to reduce the repulsive interaction, explaining the smaller E_{def} of **Zn-CAT-(NO$_2$)$_{100}$** than that of pristine **Zn-CAT**, hence decreasing the gate-opening pressure. Indeed, the **–NO$_2$** groups do not exist in a

repulsive position after C_2H_2 adsorption (Supplementary **Fig. 47d**). These results indicate that introducing substituents into parent MOFs can tune the flexibility of MOFs and readily change the E_{def} of the framework upon gas adsorption, making it possible to control the gate-opening gas adsorption, as observed from the experimental results.

Optimal conditions

Owing to the insight into the structural dynamics of our system obtained from the combination of various characterisation techniques and theoretical calculations, the amino group efficiently adjusted both P_{go} and P_{gc} for practical use at different temperatures (**Fig. 4**). Due to the limitation of actual physisorption instruments to 100 kPa pressure, we built a system capable of recording the acetylene physisorption at a higher pressure than 100 kPa, which was not been seen before (Supplementary **Fig. 37**). The optimal compressed condition must not exceed 200 kPa due to the acetylene explosive behavior above this pressure. The discharge gas should happen above 100 kPa because the gas would not flow automatically below this pressure. Thus, it is possible, with this solid-solution system, to fill at low temperature to achieve high adsorption amount at low gate opening pressure while releasing at room temperature above 100 kPa. The optimal conditions for the safe handling and use of compressed pure acetylene gas were tested for **Zn-CAT-$(NH_2)_{60}$** with a maximum released gas of 66 v/v at 100 kPa and 310 K (which is 67 % of the cylinder content) and **Zn-CAT-$(NH_2)_{100}$**, which allowed the release of 77 % of the cylinder content (~ 90 v/v) at 100 kPa and 298 K (**Fig. 4** and Supplementary **Fig. 44**).

Our system has three main advantages compared to the state-of-the-art materials. First, when comparing the usable storage capacity of acetylene for **Zn-CAT-$(NH_2)_{100}$** with the reported MOFs, our material provides an USC of ~ 90 v/v at 150 kPa and degassing at 100 kPa, both at 298 K, which is the highest among the reported MOFs (**Fig. 4c** and Supplementary **Table**

5). Second, **Zn-CAT-(NH$_2$)$_{100}$** achieves 77% of the amount released at 100 kPa, which is a crucial indicator of safety, as the unused or trapped acetylene is potentially dangerous (**Fig. 4c**). Compared to the MOFs reported for their high adsorption capacity, all retained at least 50 % of acetylene in their pores. Third, the recyclability tests did not show any change in the uptake or release capacity, which is in contrast with the conventional zeolite-type adsorbents that cannot be reused without strong heating reactivation (Supplementary **Fig. 48-49**).

For industrial development, we demonstrated that our flexible MOF adsorbents exhibit the following practical advantages for storing acetylene compared to the current solvent compression method (**Fig. 4d**). High acetylene purity is achieved as no solvents that can degrade or contaminate are present. The functionalized **Zn-CAT-(X)$_n$** can compress large quantities of acetylene (~ 117 v/v) at less than 200 kPa, allowing the development of smaller gas containers at low pressure with filling controlled *via* a pressure gauge and not by mass. Compared to the solvent-free compression method, the adsorbed gas can be compressed in larger quantities in MOF pores (37-fold increase, **Fig. 4d**). Finally, the release pressure condition can be easily manageable with the % ratio of the amino group. Indeed, geographically different locations have different climates and thus different temperature regimes in which to operate the acetylene containers. Therefore, the tailor-designed of **Zn-CAT-(X)$_n$** solid solution offers tunable uptake/release pressures at a desired temperature for various gases.

Conclusion

Herein, we demonstrated the design of a functional MOF with practical gate pressures *via* a modification of the molecular framework. The designed system has a mechanism by which the substituent exchange of the ligand controls the gate pressures of the target guest molecule by

modulating the deformation energy of the interpenetrated framework. In the case of acetylene storage, these conditions were met using **Zn-CAT-(NH$_2$)$_{60}$** at 310 K and **Zn-CAT-(NH$_2$)$_{100}$** at 298 K, which allowed the release of more than 66 % of acetylene at 100 kPa. This method is versatile, as it uses readily available MOFs and achieves the required performance with only minor modifications. These results open the way for the application of flexible MOFs to the practical storage of targeted gases from the discovery of cooperative adsorption phenomena.

Methods

Materials. All chemicals were used as received without any further purification., 1,4-benzenedicarboxylic acid, 2-amino-1,4-benzenedicarboxylic acid, 2-nitro-1,4-benzenedicarboxylic acid, 4,4´-bipyridine were purchased from TCI. Zinc nitrate hexahydrate, Ethanol (EtOH), dimethylformamide (DMF) and other materials were purchased from Nacalai Tesque.

Synthesis of Zn-CAT and **Zn-CAT-(X)$_n$ MOF series.** The syntheses of **Zn-CAT** and **Zn-CAT-(X)$_n$** series (***n*** = 0 to 100% and **X** = –**NH$_2$**, –**NO$_2$**) were conducted following a method previously published and can be produced in 100 g scale.[37] Specifically, 1,4-benzenedicarboxylic acid is dissolved with the functionalized 1,4-benzenedicarboxylic acid (total 2 eq, 20 mmol) in DMF (concentration [**bdc linker**] = 0.15 M) at 373.15 K for 15 min. An ambient solution of $Zn(NO_3).6H_2O$ (2 eq, 5.94 g, 20 mmol) in DMF (concentration [**metal**] = 0.4 M) was added to the stirring mixture at 373.15 K for 10 min. 4,4´-bipyridine (1 eq, 1.56 g, 10 mmol) is dissolved at room temperature in EtOH (concentration [**pillar**] = 0.1 M) and added to the reaction mixture. The mixture was kept at 373.15 K for 24 h. After cooling down to room temperature, the resulting precipitated is collected *via* centrifugation and washed three time with DMF (3 x 40 mL) and three times with EtOH (3 x 40 mL). The material is dried under vacuum at 323.15 K for 12 h to give a white/yellow powder in ~ 90 to 98 % yields (6 to 6.9 g).

^{1}H Nuclear Magnetic Resonance (NMR) spectra. Each MOFs were dissolved in 0.75 mL of DMSO-d^6 and 10 μL of deuterated TFA. ^{1}H NMR spectra were recorded at 298.15 K at 400 MHz, where chemical shifts (δ in ppm) were determined with respect to tetramethylsilane (TMS) as an internal reference.

Thermogravimetric Analysis (TGA). Thermal stability of all MOFs were measured under nitrogen flux with a heating rate of 5 $K.min^{-1}$ from 303.15 K to 773.15 K on a Perkin Elmer STA 6000 Thermo Gravimetric Analyzer.

Powder X-ray diffraction (PXRD). PXRD measurements were performed on a Rigaku SmartLab X-ray diffractometer using Cu−Kα radiation (λ = 1.54178 Å) in the 2θ range of 3−40 ° with a scanning rate of 5 $°.min^{-1}$.

Ultraviolet-visible Absorption (UV) spectroscopy. UV spectra of all materials were measured on a JASCO V670 spectrophotometer from 700 to 200 nm. Samples were previously heated at 423 K under vacuum for 12 h before measurements.

Scanning Electron Microscopy (SEM) analyses. SEM images were collected with HITACHI SU5000 microscope using 3.0 kV acceleration voltage and 5 mm working distance. Samples were directly deposited on a carbon conductive carbon tape.

Single crystal X-ray diffraction. Measurements of single crystal X-ray diffraction data for as-synthesised and activated **Zn-CAT-$(NO_2)_{100}$** were collected on the beamline BL02B1 at the Japan Synchrotron Radiation Research Institute with 0.41270 Å radiation at 100 K and 195 K respectively. Crystals were extracted from a mixture DMF/EtOH into oil and mounted onto the goniometer for data collection. The structures were solved using *SHELXT*. Structure solution and refinement was performed within *SHELXL* on *Olex2*. Crystal information and details relating to the structural refinements are presented in Supplementary **Table 1** & **2**. Crystallographic data for as-synthesized and activated **Zn-CAT-$(NO_2)_{100}$** structures have been deposited in the Cambridge Structural Database with CCDC numbers 2036574 -2036575.respectively.

Single gas adsorption isotherms. MOF samples were prior activated through thermal activation at 423 K for 12 h before measurement. The adsorption isotherms were measured with BELSORP-CRYO (C_2H_2 and CO_2) and BELSORP-MAX (C_2H_2, CO_2, CH_4 and O_2) volumetric adsorption equipment from Bel Japan. Targeted relative pressures in the range of 0.01-100 kPa were defined and limits of excess and allowance amount were set to 5 and 10 $cm^3.g^{-1}$, respectively. Equilibrium conditions for each point were: 0.03 % pressure change within 300 s. The dead volume was determined using helium gas.

Gate opening and closing pressure and total capacity determination The gate pressure points were determined at the inflection point of the adsorption and desorption isotherms. The total capacity reported are the maximum amount of gas adsorbed by the material.

In-situ PXRD coupled with gas sorption measurements. The measurements were performed on BELSORP-18PLUS (MicrotracBEL, Japan, Corp.) automated volumetric sorption analyzers, equipped with cryostat temperature controllers. The in-situ PXRD/adsorption measurements were carried out using a Rigaku SmartLab with Cu−Kα radiation connected to BELSORP-18PLUS volumetric adsorption equipment. Those apparatuses were synchronized with each other and each PXRD pattern was obtained at each point of the sorption isotherms. The samples were prior activated through external thermal activation at 423 K for 12 h and further 2 h internal activation at 423 K before measurement.

Acetylene high pressure storage test set-up measurements. The experimental set-up used for acetylene storage measurements is shown in Supplementary **Fig. 37**. The gas manifold consisted of two lines fitted with mass flow controller. One line is used to feed an inert gas, in our case, helium gas is used as reference gas before each experiment and as gas purge after each acetylene measurement. The other line, contains pure acetylene gas. In a typical experiment, 10 g of

adsorbent powder was activated under vacuum at 423 K in a separate oven for 12 h. The vessel is filled with helium and plugged in the set-up. Before starting each experiment, the column is evacuated and heated at 423 K for 2 h before the acetylene filling at a flow rate of 50 $cm^3.min^{-1}$. The acetylene filling process was performed at low temperature (273 K or 243 K). After reaching the maximum loading, the vessel was slowly warmed to 290 K, 298 K or 310 K. The acetylene excess amount was released during the heating process. After filling, the desorption is made by vacuum pump until complete release of the gas.

Additional Information

Data availability X-ray crystallographic data have been deposited at the Cambridge Crystallographic Data Centre (http://www.ccdc.cam.ac.uk/) with reference numbers CCDC 2036574-2036575. A copy of the data can be obtained free of charge via https://www.ccdc.cam.ac.uk/structures/. All other data supporting the findings of this study are available within the article and its Supplementary Information. Data are also available from the corresponding author upon reasonable request.
