How is the LPFC activity related to the activity in MT+ in the task-irrelevant condition? The correlation coefficient between the task-irrelevant–related activity (28) in MT+ and the LPFC was ~0.90. This is in accord with the view that when the LPFC is activated, it provides direct or indirect inhibitory control on the activity of MT+.

One might think that the low performance at the 5% coherence ratio was obtained because, despite the instructions to focus on RSVP task performance, the participants may have tried to find a coherent motion direction or to detect whether coherent motion was presented. If these motion tasks are difficult, they may leave fewer resources available for the RSVP task. However, this is not likely. If the participants engaged in the search for motion direction, this task should be hardest at 0% coherence and therefore, the lowest RSVP performance should have occurred at 0% and not at 5% coherence. Second, if the participants engaged in motion detection, this task should be hardest at 5% coherence because indiscernibility may be greatest near the coherent motion threshold, and thus, in accordance with the observed RSVP performance result. However, the lowest blood oxygen level–dependent (BOLD) activity was observed at 5% coherence ratio in the LPFC and cannot be directly explained by this possibility.

The results of the present study demonstrate two important points. First, a weak task-irrelevant stimulus feature that is below but near the perceptual threshold more strongly activates the visual area (MT+) that is highly related to the stimulus feature and more greatly disrupts task performance. There was a tendency for activity in the posterior occipitotemporal sulcus (pOTs) (29, 30) and the left angular gyrus (31), which are sensitive to letters and words and may be related to the RSVP task, to be lower at the 5% coherence than at the other coherent motion ratios. This contradicts the general view that irrelevant signals that are stronger in stimulus properties have a greater influence on the brain and performance and that the influence of a subthreshold stimulus is smaller than that of a suprathreshold stimulus.

Second, the results may reveal important bidirectional interactions between a cognitive controlling system and the visual system. The LPFC, which has been suggested to provide inhibitory control on task-irrelevant signals (22–26), may have a higher detection threshold for incoming signals than the visual cortex. Task-irrelevant signals around the threshold level may be sufficiently strong to be processed in the visual system but not strong enough for the LPFC to notice and, therefore, to provide effective inhibitory control on the signals (Fig. 4A). In this case, such signals may remain uninhibited, take more resources for a task–irrelevant distractor, leave fewer resources for a given task (32, 33), and disrupt task performance more than suprathreshold signals. On the other hand, suprathreshold coherent motion may be noticed, may be given successful inhibitory control by the LPFC, and may leave more resources for a task (Fig. 4B) (22–26). This mechanism may underlie the present paradoxical finding that subthreshold task-irrelevant stimuli activate the visual area strongly and disrupt task performance more than some suprathreshold stimuli. It could also be one of the reasons why sub-threshold stimuli often lead to relatively robust effects (2, 11, 14).

**Maternal Oxytocin Triggers a Transient Inhibitory Switch in GABA Signaling in the Fetal Brain During Delivery**

Roman Tyzio,1 Rosa Cossart,1 Ilgam Khalilov,1 Marat Minlebaev,1 Christian A. Hübner,2 Alfonso Represa,1 Yehezkel Ben-Ari,3+ Rustem Khazipov1

We report a signaling mechanism in rats between mother and fetus aimed at preparing fetal neurons for delivery. In immature neurons, γ-aminobutyric acid (GABA) is the primary excitatory neurotransmitter. We found that, shortly before delivery, there is a transient reduction in the intracellular chloride concentration and an excitatory-to-inhibitory switch of GABA actions. These events were triggered by oxytocin, an essential maternal hormone for labor. In vivo administration of an oxytocin receptor antagonist before delivery prevented the switch of GABA actions in fetal neurons and aggravated the severity of anoxic episodes. Thus, maternal oxytocin inhibits fetal neurons and increases their resistance to insults during delivery.

Delivery is a stressful event associated with high risks to the fetal brain (1); however, whether the fetal brain prepares for delivery remains largely unknown. We addressed this issue by studying γ-aminobutyric acid (GABA)–mediated (GABAergic) signaling in the
rat hippocampus. GABA is the principal inhibitory neurotransmitter in the adult brain. However, during fetal and postnatal periods GABA has a depolarizing action (2–4) and provides the major, and often the only, excitatory synaptic input to immature neurons (5). Excitatory action of GABA is due to elevated intracellular chloride and depolarized value of the GABA type A (GABA\textsubscript{A}) reversal potential (\(E_{\text{GABA}}\)) (6–10). Excitatory GABA is pivotal in control of neuronal firing, generation of the primitive patterns of activity, intracellular calcium signaling, and neuronal development (2, 3). GABA signaling is therefore expected to be an essential element in physiological adaptation to stress during delivery.

To characterize the properties of GABA signaling during the perinatal period, we used cell-attached recordings from fetal and neonatal rat hippocampal slices [from embryonic day (E) 18 to postnatal day (P) 5; term is E21] (11). During fetal (E18 and E19) and postnatal periods (P1 to P5), activation of GABA\textsubscript{A} receptors increased the firing of action potentials in the majority of CA3 pyramidal cells [Fig. 1A; also (6, 7, 12)]. However, during a brief period extending from E20 to day of birth (P0), the proportion of cells excited by GABA sharply decreased. The loss of the excitatory effect of GABA peaked at E21 [-1 to 2 hours before delivery (Fig. 1A)].

The action of GABA depends on the direction of the transmembrane current elicited by GABA, its driving force (\(DF_{GABA}\)) being the difference between \(E_{GABA}\) and resting membrane potential (\(E_m\)). Positive values of \(DF_{GABA}\) determine excitatory actions of GABA in immature neurons (2, 3, 6, 7). To estimate \(DF_{GABA}\), we used cell-attached recordings of single GABA\textsubscript{A} channels (10) (Fig. 1, B to D), which affect neither \(E_{GABA}\) nor \(E_m\). With 1 \(\mu\)M GABA in the pipette solution, GABA\textsubscript{A} channels were observed in ~90% of patches (\(n = 553\)) but not in the presence of the GABA\textsubscript{A} receptor antagonist picrototoxic (100 \(\mu\)M; \(n = 25\) (Fig. 1B)). We found that \(DF_{GABA}\) is strongly depolarizing in fetal and postnatal periods (Fig. 1D). However, \(DF_{GABA}\) negatively shifted during a brief near-term period (from E20 to P0), switching to a hyperpolarizing value of \(-8.4 \pm 2.5\) mV at term [mean ± SEM, \(n = 34\) (Fig. 1D)]. Thus, the disappearance of GABA-mediated excitation at term (Fig. 1A) coincides with a switch in polarity of GABA signals.

The perinatal changes in \(DF_{GABA}\) could be due to a negative shift of \(E_{GABA}\) or to a depolarizing shift of \(E_m\). By using cell-attached recordings of single N-methyl-D-aspartate (NMDA) channels as voltage sensors (13, 14), we found that during early fetal and postnatal periods \(E_m\) is \(-78.7 \pm 1.9\) mV (\(n = 42\); pooled data for E18 and E19 and P1 to P5) [also (13, 14)], but near term there is a small hyperpolarizing shift to \(-85.4 \pm 1.5\) mV (\(n = 14\) at birth (Fig. 1B)). Knowing \(DF_{GABA}\) and \(E_m\), we calculated \(E_{GABA}\) (\(E_{GABA} = DF_{GABA} + E_m\)) and found that \(E_{GABA}\) switches from \(-40\) mV at E18 to \(-92\) mV at E21 and then returns to depolarizing values shortly after birth (Fig. 1F). This corresponds to a decrease in [Cl\textsuperscript{-}] (intracellular chloride concentration) from 18 mM to 4 mM (Fig. 1F).

Because GABA-induced depolarization raises [Ca\textsuperscript{2+}] ([12, 15–18]), we used a multibeam two-photon microscope to monitor [Ca\textsuperscript{2+}] changes in hundreds of CA3 neurons in slices loaded with the calcium indicator fura 2-AM (Fig. 2). The GABA\textsubscript{A} receptor agonist isoguvacine (10 \(\mu\)M) elicited a robust increase of [Ca\textsuperscript{2+}] in the majority of neurons at E18 and at P2 to P4 [average of 56 ± 3%, \(n = 7\) movies and 931 cells (Fig. 2, B to D)]. In contrast, at E21 to P0, [Ca\textsuperscript{2+}] increased in only 31 ± 6% (\(n = 10\) movies and 1546 cells, \(P < 0.01\)) cells. Isoguvacine also decreased the frequency of spontaneous calcium spikes.

![Fig. 1](https://www.sciencemag.org/science/vol314/issue5800/)

**Fig. 1.** Transient perinatal loss of the GABA\textsubscript{A}-mediated excitation. (A) Responses of CA3 pyramidal cells recorded in cell-attached mode to the GABA\textsubscript{A} agonist isoguvacine. Below, summary plot of the proportion of cells excited by isoguvacine during the perinatal period. There is a transient loss of the excitatory effect of isoguvacine near term. Red corresponds to the fetuses whose mothers received SSR126768A. E21 corresponds to the early phase of delivery (1 to 2 hours before birth); P0 is the day of birth; pooled data from 146 neurons.) (B) Cell-attached recordings of single GABA\textsubscript{A} channels with 1 \(\mu\)M of GABA in patch pipette (top trace); the channels were not observed in the presence of the GABA\textsubscript{A} antagonist picrototoxic (100 \(\mu\)M; bottom trace). (C) \(I-V\) relationships of the currents through GABA\textsubscript{A} channels in two cells at E21 and E18; their reversal potential corresponds to \(E_{GABA}\). (D) Summary plot of the age dependence of \(DF_{GABA}\), inferred from single GABA\textsubscript{A} channels recordings [mean ± SEM; 209 CA3 pyramidal cells (○) and 17 neocortical pyramidal cells (□); 6 to 24 patches for each point]. Red indicates pretreatment with SSR126768A (n values are 25 hippocampal and 9 neocortical patches). (E) Age dependence of the resting membrane potential (\(E_m\)) of CA3 pyramidal cells inferred from the reversal of single NMDA channels recorded in cell-attached mode (\(n = 84\) cells; 4 to 12 patches for each point). (F) Age dependence of the GABA\textsubscript{A} reversal potential (\(E_{GABA} = E_m + DF_{GABA}\)). There is a transient hyperpolarizing shift of \(E_{GABA}\) near birth.
events in many neurons near term [9 ± 2% (Fig. 2)]. Thus, during delivery, the ability of GABA to increase [Ca^{2+}] is significantly reduced.

What underlies the near-term switch in GABA actions? Because this phenomenon is not observed in fetal neurons grown in culture (8, 9), we hypothesized that it is related to parturition and in particular to maternal hormones released during delivery. Parturition is initiated by a massive release of oxytocin (19). In addition to its pivotal role in parturition, there are also indications that oxytocin exerts multiple effects in the adult central nervous system (19–25). Maternal oxytocin easily crosses the placenta to reach the fetus (26), suggesting that oxytocin may be responsible for the hyperpolarizing switch in action of GABA in fetal neurons during delivery. With selective antibodies, we found a high density of oxytocin receptor immunoreactivity in the hippocampus and neocortex during the perinatal period (Fig. 3A and figs. S1 and S2). During cell-attached recordings from slices at E18 and P2, applications of oxytocin (1 μM) induced a negative shift in ΔF/Δt (Fig. 3C and D) and suppressed GABA-mediated excitation (Fig. 3B). The effects of oxytocin were completely prevented by bath application of the selective oxytocin receptor antagonist atosiban (AT, 1 to 5 μM) (Fig. 3D). At term, application of oxytocin did not cause a significant effect on the hyperpolarizing ΔF/Δt (Fig. 3D), suggesting that the effects of exogenous oxytocin are occluded by the endogenous hormone. In keeping with this hypothesis, we found that atosiban switched ΔF/Δt from hyperpolarizing to depolarizing at term but not in fetal and postnatal neurons (Fig. 3D). Moreover, intracardial perfusion of E21 fetuses with artificial cerebrospinal fluid (ACSF, to wash out endogenous hormone) produced a similar shift of ΔF/Δt from hyperpolarizing to depolarizing (fig. S3). Addition of 1 μM oxytocin at the end of the perfusion restored hyperpolarizing values of ΔF/Δt (fig. S3). Therefore, endogenous oxytocin is present in slices at term and provides tonic activation of oxytocin receptors, leading to the shift of ΔF/Δt. We also found that the negative shift in ΔF/Δt from 38.4 ± 6.2 mV (n = 8) to -7.2 ± 2.2 mV (n = 18) occurred in E18 fetuses obtained from mothers treated with oxytocin (50 μg/kg) during 2 hours before cesarean delivery.

To directly measure the effects of oxytocin on [Cl^-], we used two-photon chloride imaging in slices loaded with a chloride-sensitive dye, MQAE (Fig. 3, E and F) (27). In E18 and P4 slices, oxytocin (1 μM) produced a significant increase in the baseline fluorescence signal in half of the imaged cells, indicating a strong reduction of [Cl^-], (average of 43 ± 4%, n values of 10 movies and 1792 cells (Fig. 3F)), and the effect was prevented by atosiban (5 μM; reduction of [Cl^-], in 5 ± 3% cells, n values of 2 movies and 435 cells). Furthermore, incubation of P4 slices with oxytocin reversed the effect of isoguvacine on spontaneous calcium events [59 ± 17% imaged cells not activated by isoguvacine, n values of 3 movies and 228 cells (fig. S4)]. Thus, the effects of oxytocin fully matched the changes in GABA signaling occurring at term. This result indicates that oxytocin is sufficient to trigger changes of [Cl^-].

To determine whether endogenous oxytocin is necessary for the near-term switch in the action of GABA, we treated pregnant rats orally with the selective oxytocin receptor antagonist SSR126768A (28) (1 mg/kg, starting from E20) and measured the consequences at term. Cell-attached recordings revealed major differences between treated and age-matched control pups, including strongly depolarizing values of ΔF/Δt (Fig. 1D, red circle) and a high proportion of cells excited by GABA (Fig. 1A, red circle). Similar effects were also observed in neocortical neurons, in which ΔF/Δt was -9.4 ± 3.4 mV in control rat pups (n = 8) and 28.3 ± 3.7 mV (n = 9) in pups of mothers pretreated with SSR126768A (Fig. 1D). Thus, maternal oxytocin is necessary and sufficient to trigger the near-term switch in GABA action in the hippocampus and neocortex.

What are the mechanisms underlying the oxytocin-mediated reduction of [Cl^-] at term? Because the NKCC1 chloride inward cotransporter is responsible for elevated [Cl^-], in immature neurons (4, 7, 29, 30), we tested the effects of the selective NKCC1 antagonist bumetanide. We found that bumetanide (10 μM) produces a robust negative shift of ΔF/Δt and occludes the effects of oxytocin (fig. S5). The short latency of oxytocin actions (Fig. 3F) and the observation that blockade of oxytocin receptors does not alter chloride transporters gene expression (fig. S6) suggest that the hormone down-regulates NKCC1 activity. Hypoxic-ischemic brain damage is a principal cause of newborn death and neurological impairment (7). We hypothesized that the excitatory-to-
inhibitory switch in GABA signaling reduces neuronal activity and metabolic demand, thus helping to protect fetal neurons from hypoxic insults (31). Episodes of anoxia and aglycemia were induced by superfusion with a solution in which oxygen was substituted for nitrogen and glucose was substituted for sucrose. The onset of anoxic depolarization (AD) that is an electrophysiological marker of neuronal death (31, 32) was measured by using extracellular field potential recordings in the intact hippocampi of E21 rats in vitro after various treatments in vivo to the mother and/or to the fetuses intracardially before the in vitro experiment (Fig 4). In control fetuses, AD occurred after 55.6 ± 1.4 min (n = 30) of perfusion with the anoxic-aglycemic solution (Fig. 4). In the hippocampi prepared from the fetuses intracardially perfused with atosiban (5 μM; n = 15) or from the fetuses whose mothers received SSR126768A (1 mg/kg; n = 19), AD onset was significantly accelerated to 44.1 ± 1.1 min (n = 34; P < 0.01). Bumetanide (10 μM) applied in the presence of the oxytocin receptor antagonists delayed AD to the control values (53.4 ± 1.7 min; n = 18; P < 0.01). Bumetanide (10 μM)
occluded the effects of the oxytocin receptor antagonists and restored the control delays (53.4 ± 1.7 min, n = 18; P < 0.01). These data indicate that maternal oxytocin exerts a neuroprotective action on fetal neurons during parturition and that this action is likely due to a reduction of [Ca2+].

Our results suggest that oxytocin, in addition to its well-established role in labor and lactation and its multiple effects in the adult central nervous system (19–25), also exerts a powerful action on fetal neurons. This mechanism adds a previously unknown facet to the plasticity of GABA signaling on fetal neurons during parturition and that this action is likely due to a reduction of [Ca2+].

ATP Release Guides Neutrophil Chemotaxis via P2Y2 and A3 Receptors

Yu Chen, Ross Corridd, Yoshiaki Inoue, Linda Yip, Naoyuki Hashiguchi, Annelies Zinkenager, Victor Nizet, Paul A. Insel, Wolfgang G. Junger†

Neutrophils are primary phagocytic cells with important roles in host defense and tissue repair. However, activated neutrophils damage host tissues and contribute to chronic inflammatory diseases, including rheumatoid arthritis, inflammatory bowel disease, and asthma (1). A key feature of neutrophils is their ability to detect and migrate to compromised tissues by following a concentration gradient of chemotactic substances released from microbial pathogens or injured cells.

Neutrophils can respond to chemoattractant gradients that differ in concentration by as little as 1% across the length of the cell body (2). Chemotaxis must involve signal amplification because a strongly polarized distribution of intracellular signal-transduction components is observed even in shallow gradients. The mechanisms of signal amplification are unclear (3, 4). We identified the polarized release of adenosine triphosphate (ATP), the activation of P2Y2 receptors, and the translocation and activation of A3 adenosine receptors as key mechanisms of signal amplification that control cell orientation and direct the migration of neutrophils.

Membrane deformation caused by mechanical or osmotic stress induces the release of cellular ATP from mammalian cells; however, detailed information on the underlying mechanisms is lacking (5, 6). Because cell migration also involves membrane deformation, we tested whether the stimulation of human neutrophils with the chemoattractant N-formyl-Met-Leu-Phe (FMLP) causes ATP release. Treatment of cells (104 cells in 250 μl of solution) with 100 nM FMLP rapidly tripled extracellular ATP concentrations in bulk media (Fig. 1A). Neutrophils completely hydrolyzed ATP in 30 min (Fig. 1B), which is consistent with the presence of ecto-adenosine monophosphate (AMP) and adenosine peak at 5 min after FMLP stimulation; but while the concentration of ATP returned to basal levels after 15 min, AMP and adenosine concentrations remained >5-fold above baseline (Fig. 1B), which is consistent with the presence of ecto–adenosine triphosphatases (ecto-ATPases) (7, 8). Neutrophils completely hydrolyzed exogenous ATP (5 μM) within 2 min after ATP addition, which suggests that they have potent ecto-ATPase activity (Fig. 1C).

Because membrane deformation occurs predominantly at the leading edge closest to the chemoattractant source, we hypothesized this region to be the principal site of ATP release. Fluorescent microscopy that was used to visualize ATP release (9) showed that the principal site of ATP release is the leading edge closest to the chemoattractant source (10). We tested the effect of apyrase, which hydrolyzes ATP, on chemotaxis in a trans-well system composited of upper wells with neutrophils and lower wells with 1 μM FMLP separated by a filter with 3-μm pores. Addition of apyrase to the upper wells reduced chemotaxis by nearly 100% (Fig. 2A).
