Résumé. — Des spectres de diffusion inélastique des neutrons, à Q constant, ont été effectués, avec une très bonne résolution, près de la transition de phase Oh₁h ~ D₁₈₄h à 193 K dans RbCaF₃. Nous avons observé un pic central dont l’intensité varie considérablement en fonction de la température, à q = q₁. Nous avons mesuré les paramètres λ₁, λ₂ et λ₃ qui caractérisent l’anisotropie des nappes de dispersion près du mode R₂₅ à différentes températures. En tenant compte de l’importante anisotropie des facteurs de structure dynamiques des 3 modes issus du mode mou R₂₅, nous avons déterminé les 4 paramètres inconnus (A, ω₂, Γ, δ²) de la fonction de réponse utilisée par Shapiro et al. dans l’étude de SrTiO₃ en ajustant les courbes calculées aux courbes expérimentales. Nous donnons les courbes de variation de ω₂ et de δ² en fonction de la température ; δ² décroit quand (T - T_c) croît. Sur la base de nos résultats, nous discutons de la validité de la dépendance en q et T de la fonction de réponse.

Abstract. — High resolution inelastic neutron scattering constant Q scans have been performed near the 193 K cubic (Oh₁h) to tetragonal (D₁₈₄h) phase transition in RbCaF₃. A divergent temperature dependent central peak was observed at q = q₁. The parameters λ₁, λ₂ and λ₃ characterizing the anisotropy of the dispersion map in the vicinity of the R₂₅ mode have been measured at different temperatures. Taking into account the large anisotropy of the dynamical structure factors of the 3 modes belonging to the R₂₅ soft mode, the 4 unknown parameters (A, ω₂, Γ, δ²) of the spectral response used by Shapiro et al. in SrTiO₃ were determined by fitting the calculated scans with the experimental ones. The temperature dependence of ω₂ et δ² is reported ; δ² is found to decrease when (T - T_c) increases. The validity of the q and T dependence of the spectral response function is discussed on the basis of our results.

1. Introduction. — The observation of a temperature dependent central peak centered around ω = 0 in addition to the soft phonon sidebands was first mentioned in 1971 by Riste et al. [1] in the study of SrTiO₃. Since that time this behaviour has been extensively studied, particularly in some perovskite type compounds such as SrTiO₃ [2], LaAlO₃ [3] and KMnF₃ [2]. One of the main problems in the interpretation of this unexpected phenomenon is to detect whether it is an intrinsic effect or if it is due to impurities [4].

In KMnF₃, the overdamped nature of the phonons prevented detailed studies. So in the perovskite structure quantitative information is available only for ABO₃ compounds. Therefore, until to-day it has been impossible to compare the central peak behaviour of ABO₃ and AMF₃ perovskite in which the possible defects should be different. The purpose of the present work is twofold : to provide quantitative description of the soft phonon and central peak parameters for an overdamped system, and to study the central peak behaviour in a fluoperovskite compound.

The organization of the present paper is as follows.

The experimental conditions of the inelastic neutron scattering experiments are described in section 2. In order to minimize the number of fitted parameters in the deconvolution process we have measured the anisotropy of the phonon dispersion surface around the R_{25} mode at different temperatures (section 3). Then, taking into account the strong anisotropy of the dynamical structure factors of the three modes belonging to the R_{25} soft mode, we were able to analyse our data with the same spectral response function as used by Shapiro et al. in SrTiO_3. Finally, in section 4 these results are discussed and compared with those of Shapiro et al. for SrTiO_3.

2. Experimental. — We have grown a single crystal of RbCaF_3 by the Bridgman-Stockbager technique with a temperature gradient of 8°/cm inside the furnace and a vertical displacement of the sample of 15-20 mm per 24 hrs [5]. The crystal obtained had a volume of 2 cm^3 and its mosaic spread was less than 3° of arc.

First inelastic neutron scattering measurements were carried out on the H4 spectrometer at the Saclay reactor. Then most of the data were taken on the IN2 thermal-beam three axis spectrometer at the I.L.L. high flux reactor. Incident energies of 15 and 5 meV were used with pyrolytic graphite (002) monochromators. Higher-order contamination was reduced to a negligible level using a pyrolytic graphite filter at the higher energy and a cooled beryllium filter at the lower energy combined with a Ge (111) as analyser. The contribution from the incoherent scattering was measured and subtracted from all the data. The parameters of the resolution ellipsoid were fully determined experimentally, then the collimations were adjusted by fitting the calculated resolution function with the experimental one.

In the classical (hhh) scattering plane some interesting modes cannot be observed, so in order to determine the curvatures of the phonon dispersion surface in the vicinity of the R_{25} mode in the R-X, R-M and R-Γ directions, the data were collected in the two scattering planes described in figure 1. The crystal was mounted so that it was possible to pass from one plane to the other by rotating the crystal around a [311] horizontal axis.

The specimen temperature was controlled to within 0.03 °K but we could not avoid the occurrence of a small vertical gradient.

3. Results. — 3.1 Dispersion Branches along the R-M Line. — Room temperature measurements of the low energy branches along the R-M line were performed on the 3-axis spectrometer IN8 (ILL). The experimental points represented on figure 2 are peak positions. Owing to the large damping of the T_2 mode (and T_5 in the neighbourhood of the R point) the peak positions are lower than the corresponding quasi-harmonic frequencies; the change is of the order of 0.2 THz (0.82 meV). The T_2 and T_5 phonon branches are very similar in KMnF_3 and RbCaF_3. In these two crystals the first branch is nearly flat while the T_5 branch presents a strong curvature.

3.2 Phonon Dispersion Surface around the R_{25} Mode. — The knowledge of both the dynamical structure factors of the mode (first part of this work) and the resolution function enables us to choose the points of the reciprocal lattice where a phonon of a given symmetry must be intense and well focussed. Taking into account measurements in the P_1 and P_2 scattering planes previously defined, we were able to determine the curvature of the modes λ_1, λ_2, λ_3, T_2, T_5, S_1, S_2 and S_3 near the R_{25} mode, at different temperatures. From these, we deduced the values of λ_1, λ_2, λ_3 and their temperature dependence (Table I).

The determination of the curvature of the mode is not easy because it is strongly dependent on the position of the $R_{25}$ phonon which is itself dependent on $\lambda_1$, $\lambda_2$ and $\lambda_3$ so we had to use a self-consistent method. $\lambda_1$, $\lambda_2$ and $\lambda_3$ measured in this way are somewhat different from the calculated ones (former paper) but we may notice that the measured values are taken at $|q - q_R| \approx 0.1 q_R$ whereas the calculated values are derived from the limit $(q - q_R \to 0)$. Some scans used for the $\lambda_i$ determination at $T = 254$ K are shown in figure 3.

FIG. 3. — Typical energy profiles of some phonons used in the experimental determination of $\lambda_1$, $\lambda_2$ and $\lambda_3$ at 254 K. The black points are measured values; the dotted lines represent the best fitting cross section $S(q, \omega) = F(q) |F(q)|^2$ which is broadened by instrumental corrections to give the solid lines.

3.3 SOFT PHONON AND CENTRAL PEAK. — High-resolution constant $Q$ scans were made at the $(0.5 - 0.5 1.5)$ $R$ point of the $P_1$ scattering plane and at the $(1.5 0.5 0.5)$ $R$ point of the $P_2$ scattering plane. Figure 4 shows a part of these measurements. We may notice that a divergent central peak rises out of the broad overdamped phonon as in KMnF$_3$ [2]. The linewidth of the observed central peak (FWHM ~ 0.025 to 0.03 THz) is always smaller than the resolution width given by the vanadium (FWHM = 0.04 THz).

We analysed these data with the same spectral response of a soft mode $q$ as used by Shapiro et al. for SrTiO$_3$ [2]:

$$S(q, \omega) = \frac{k_B}{\pi} \frac{T}{\Gamma_0} \left[ \frac{\Gamma_0}{\omega_0^2 - \omega^2} \right]^2 + \frac{\delta^2(T)}{\omega_0^2(q, T) \omega_0^2(q, T)} \frac{\gamma'}{\omega^2 + \gamma'^2}.$$
We recognize in the first term the familiar damped harmonic oscillator response where 
\[ \omega_0^2(q, T) = \omega_0^2(q, T) - \delta^2(T) \]
is the square of the renormalized mode frequency in the limit \( \omega \to 0 \), whereas \( \omega_0(q, T) \) is the quasiharmonic frequency of the mode. The second term represents an extra response of the phonon fluctuations (central peak).

Since the observed energy line width of the central peak was always resolution limited, we consider the central peak as a delta function. So we replace \( \frac{\gamma^2}{\omega^2 + \gamma^2} \) by \( f(\omega) \) with \( f(0) = 0 \) for \( \omega \neq 0 \) and \( f(0) = C \) for \( \omega = 0 \). The constant \( C \) was fixed at \( \pi \) by normalization.

On these bases, and provided that the \( \sigma_2 \) parameter is not a function of \( q \) the entire \( q \) dependence of \( S(q, \omega) \) is determined by the \( q \) dependence of the phonon frequency given by 
\[ \omega_0^2(q, T) = \omega_0^2(0, T) + A(n, T) | \eta |^2 \eta = \eta \]
where \( A(n, T) \) are the eigenvalues of the \( A(n) \) matrix (defined in the first part of this work) in which \( A_1, A_2 \) and \( A_3 \) are temperature dependent (Table I). Both model calculation and experimental determination of the \( A_i \) show that \( A_3 \) is not negligible. So in order to take into account the large anisotropy of the dynamical structure factor around the \( R_{25} \) mode, we did not use the simplification outlined by Shapiro et al.

Then, for each setting of the spectrometer \((q_0, \omega)\) the neutron intensity can be calculated by analytically performing the convolution of the scattering cross section with the four-dimensional resolution function \( R(q - q_0, \omega - \omega_0) \) previously discussed in detail by Cooper and Nathans [6] and Dorner [7].

\[ R(q_0, \omega_0) = A \int \int \sum_{j=1}^{3} | F_j(Q) |^2 S_j^2(q_j, \omega) \times R(q - q_0, \omega - \omega_0) dq dq' \rho \rho' . \]

In this expression, \( A \) is a normalization constant and according to Dorner, \( R(q - q_0, \omega - \omega_0) \) includes the ratio \( \rho_k, k_2, k_3 \) (\( k_1, k_2 \) and \( k_3 \) are respectively the initial and final values of the wave vector of the neutrons).

In the course of the integration, the dynamical structure factor \( F_j(Q) \) was calculated, for each \( q \), by diagonalizing the \( A(n) \) matrix.

The 4 unknown parameters \( A, \omega_0^2(0, T), \Gamma_0 \) and \( \delta^2(T) \) were determined by fitting the calculated scans with the experimental ones corrected by subtracting the background and the incoherent scattering. In a first step, \( A, \omega_0^2(0, T) \) and \( \Gamma_0 \) are determined between 250 K and 300 K, with incident neutron beam of 15 meV, in the domain where no contribution of the central peak was observed. As expected, we obtained values of \( A \) and \( \Gamma_0 \) without any significant temperature dependence. Some typical scans are shown in figure 5a. Thus we take:

\[ \Gamma_0 = 3.55 \text{ meV}. \]

Then at lower temperature, for the high resolution scans, \( \Gamma_0 \) was fixed and we determined \( A \) and \( \omega_0^2(0, T) \) by fitting the phonon wings of the scans. Finally, once \( A \), \( \omega_0^2(0, T) \) and \( \Gamma_0 \) are known, \( \delta^2(T) \) was calculated from the central peak alone (Fig. 5b).

Figure 6 shows the temperature dependence of \( \delta^2 \) and \( \omega_0^2 \) obtained by this method. The uncertainty in the determination of these parameters is partly due to the fluctuations of the normalization parameter \( A \) from its mean value \( \langle A \rangle \). From these curves, we conclude that for \( T - T_c > 57 \text{ K} \), \( \delta^2 \) may be taken as equal to zero. In order to confirm this result, we have done a high resolution constant \( Q \) scan at the \((0.5 - 0.5 1.5) \text{ R point for } T - T_c = 62 \text{ K}. \) As expected, we did not observe any narrow peak around \( \omega = 0 \) (Fig. 5b).

4. Discussion. — In spite of the fact that the phonon is overdamped for \( T - T_c < 70 \text{ K} \), the method of treating the data described in section 3.3 seems to give reliable results for \( T - T_c > 10 \text{ K} \). As previously observed by Shapiro et al. in SrTiO\(_3\) [2], the temperature dependence of \( \omega_0^2(0, T) \) exhibits two different behaviour patterns. For \( T > 250 \text{ K} \), where no central peak is observed, the temperature dependence of the frequency obeys the following relation

\[ \omega_0^2(0, T) = a(T - T_0) \]

with \( a = 0.13 \pm 0.05 \text{ meV}^2/\text{K} \) and \( T_0 = 212 \pm 2 \text{ K} \). In this mean-field region, we may notice that the temperature dependence of RbCaF\(_3\) and KMnF\(_3\) are similar \((a = 0.11 \pm 0.02 \text{ meV}^2/\text{K} \) for KMnF\(_3\)) whereas it is somewhat different in SrTiO\(_3\) \((a = 0.19 \text{ meV}^2/\text{K} [2])\). On the other hand, \( \omega_0^2(0, T) \) deviates from a linear temperature behaviour for \( T - T_c < 75 \text{ K} \), in the region where the central peak is observed. So we may conclude that the critical behaviour of \( \omega_0^2(0, T) \) is strongly related to the occurrence of a central peak.

With respect to the central peak, the main result of our work consists in the temperature dependence of \( \delta^2 \) which is drastically different from the one obtained in SrTiO\(_3\) by Shapiro et al. In fact, our investigations lead us to conclude that this behaviour depends on the way of performing the deconvolution. In our case, when neglecting \( \omega_2 \), \( \omega_0^2(0, T) \) is lowered by about 0.1 meV\(^2\) and the temperature dependence of \( \delta^2 \) becomes nearly the same as in SrTiO\(_3\). It is worth noticing that RbCaF\(_3\) is the first example in which \( \delta^2 \) decreases when \( T - T_c \) increases. This type of behaviour was recently predicted theoretically by
Halperin and Varma [4] in considering defects as a cause of the central peak. Nevertheless, the model of Halperin and Varma predicts $\delta^2 \propto 1/T$ whereas the present results indicate a value of $\delta^2$ which decreases much more rapidly with $T$.

The satisfactory agreement between the calculated scans represented by full lines and the experimental data (Fig. 5) is a good test for the validity of the response function $S(q, \omega)$ in which the soft mode damping $g_0$ is temperature independent. In order to test the assumption according to which $\delta^2$ is independent of $q$, we have done several constant $\omega = 0$ scans around the R point in the R-X and R-M directions, at different temperatures. For a given mode $j$ belonging to the $R_{25}$ mode, the $q$ linewidth of the central component response function is proportional to $|\Delta J(q, T)|^{-1/2}$. Owing to the triple degeneracy of the $R_{25}$ soft mode these scans are not easily interpreted. In fact, the scan along R-M ($Q_R = 1.5 0.5 0.5$, $T = 210$ K) is a sum of two contributions :

$$T_2 (A = 14 \text{ meV}^2 \text{ Å}^2, \ |F(Q)|^2 = 1)$$

and

$$T_3 (A = 875 \text{ meV}^2 \text{ Å}^2, \ |F(Q)|^2 = 1)$$

whereas the scan along R-X is a sum of three contributions :

$$S_1 (A = 638 \text{ meV}^2 \text{ Å}^2, \ |F(Q)|^2 = 0.5),$$

$$S_2 (A = 875 \text{ meV}^2 \text{ Å}^2, \ |F(Q)|^2 = 1)$$

$$S_3 (A = 252 \text{ meV}^2 \text{ Å}^2, \ |F(Q)|^2 = 0.5).$$

So, we immediately see that in spite of the weak $q$ dependence of the very low frequency $T_2$ branch we observe, on the $\omega = 0$ scan in the R-M direction, a narrow peak centered at $q = q_0$ due to the contribution of the strongly $q$ dependent $T_2$ mode. Thus, the $q$ width of these scans cannot be simply related to the $q$ extension of the central peak. As an example cons-

FIG. 5. — Scattered neutron spectra of RbCaF$_3$ at several temperatures. The full lines represent the fitted scans, the dashed curve is a plot of the spectral response $S(q_0, \omega)$ and the dotted line represents the level of the room background. All incoherent scattering has been subtracted. $a)$ Soft phonon profiles obtained with $k_I = 2.672$ Å$^{-1}$. $b)$ Typical high resolution critical scattering spectra profile.
Temperature dependence of $\omega_0^2$ and $\delta^2$ in RbCaF$_3$.

- Important $\omega = 0$ scans along the R-M line are given in figure 7 for two different temperatures. The dashed lines are not obtained from a deconvolution but simply represent the quantity

$$\sum_j S\left(\mathbf{q} \cdot 0\right) |F_j(\mathbf{Q})|^2$$

where the structure factors are calculated from the model described in the former paper. Moving away from the transition temperature (from $T = 195$ K to $T = 210$ K) the $q$ width of the central peak is broadened.

ed by the $T_2$ mode. This change is qualitatively reproduced by the calculated curve but complete quantitative agreement is clearly not obtained by means of this too simple calculation and we are going to deconvolute these scans in order to come to a conclusion about the $q$ dependence of $\delta^2$.

Acknowledgments. — The authors are indebted to R. Currat for the computer program which was used in performing the resolution function corrections. They would like to thank B. Dorner for stimulating discussions and P. Flores for his invariably kind technical assistance during the course of the measurements.
