1. Introduction.

The metal dielectric inhomogeneous media are among the most interesting materials of the last ten years. Their interest lies in their numerous applications to many disciplines, and more specifically to physics. Their optical (high frequency) and electrical (zero frequency) properties show large variations as a function of the volume fraction, the size and shape and the statistic distribution of metallic inclusions. These variations are of particular interest around the critical metallic volume fraction \( q_c \) corresponding to the electrical percolation. One also observes for values of the order of \( q_c \), an optical cross-over where a transition occurs between a dielectric and a metallic behaviour. Moreover, at constant volume fraction (in a large fraction range) the dielectric function, as a function of frequency, exhibits a resonance, the so-called dielectric anomaly.

Our aim, in this paper, is to show how these properties depend on the nature of the metallic inclusion in the compound : noble metal or transition metal. The discussion is based on experimental results on Au-MgO and Pt-Al\(_2\)O\(_3\) thin films prepared by co-sputtering. Their optical properties, electrical properties and structures are compared. The dielectric function deduced from optical measurements is analysed using two effective medium theories derived from the Maxwell Garnett [1] and Bruggeman [2] approaches, the efficiencies of which are eventually compared.

Regarding the electronic structure Au [3] and Pt [4] and more generally noble and transition metals essentially differ in the position of the Fermi level with respect to the d band. In Au the d-band is completely filled, whereas \( E_F \) cuts the d-band in Pt. Consequently, the absorption edge, characteristic of the interband transition onset, which is clearly visible in the imaginary part of the dielectric function, is situated around 2.45 eV in Au while it is shifted towards much lower energies (around 0.1 eV) in Pt. In other words, the near infrared behaviour of the dielectric function is essentially governed by intraband transitions of the conducting electrons in Au and still largely dominated by interband transitions in Pt. These well-known considerations will be important in the discussion of the optical properties of the granular films. Section 2 is devoted to the preparation and the characterisation
of the Au-MgO and Pt-A12O3 thin films. In section 3, the optical properties are discussed and analysed with the two effective medium models.

2. Preparation and characterization of the inhomogeneous films.

2.1 PREPARATION. — The inhomogeneous thin Au-MgO and Pt-A12O3 thin films were prepared with neighbouring but slightly different techniques.

Au-MgO [5] films were deposited by reactive cosputtering (Magnetron source) onto optically polished glass substrates. The target is a rectangular magnesium foil with circular holes of diameter 3 mm. The holes are filled with gold cylinders. The composition of the film can thus be varied over a wide range according to the number of holes in the target (24-80). Three substrates can be placed at 6 cm front of the target on a doubly rotating system. Each substrate rotates on its own axis at 32 rev. min⁻¹, to ensure that the film thickness is uniform, and the three substrates rotate about the axis of the chamber at 11 rev. min⁻¹, to homogenize the composition of the deposit. The substrates can be heated to 200°C. The sputtering conditions are as follows: argon pressure, 5 x 10⁻³ torr; oxygen pressure, 2 x 10⁻³ torr; rate of deposition, 35-135 Å min⁻¹ (depending on the target and the substrate temperature).

Pt-A12O3 [6] films were deposited onto optically polished glass by r.f. cosputtering. The target consists in an A12O3 disc (13 cm in diameter) with circular holes of diameter 5 mm in a hexagonal array. The holes can be filled with platinum pellets. The composition of the film can be varied over a wide range according to the number of platinum pellets in use. The substrates are located on a rotating sample holder. The films obtained by this rotating sample technique are homogeneous in composition and uniform in thickness. The rate of deposition is 50 Å min⁻¹ and the residual pressure of argon is 7 x 10⁻³ torr.

2.2 CHARACTERIZATION. — The thickness of the films with a low metallic volume fraction was determined by X-ray interference under grazing incidence. For Au or Pt volume fractions greater than 0.35 this technique failed, due to the scattering of the X-rays by the numerous metallic inclusions. A talystep mechanical step height monitor was then used.

The composition of the deposits (metallic volume fraction q) was determined for both compounds by electron microprobe analysis. In addition, chemical analysis and ESCA were performed on Au-MgO samples. In spite of the relatively poor accuracy of some of these methods, the results are in fairly good agreement.

The D.C. resistivity of the films was deduced from resistance measurements using an electrometer (before percolation) or a resistance bridge (near and after percolation).

The results of these characterizations on different samples are summarized in tables Ia et Ib.

Electrical percolation. — The plot of the resistivity versus the metallic volume fraction (Fig. 1) clearly shows that the electrical percolation occurs for the Pt-A12O3 films between 0.4 and 0.5 Pt volume fraction. The Au-MgO films do not reach this critical threshold but follow an analogous behaviour for low metal concentration. This high value of the critical volume fraction is characteristic of a 2D behaviour predicted by Monte Carlo simulations for spherical clusters [7] rather than the 3D behaviour which is expected. At least, at low volume fraction, it is indeed clear that the Euclidian dimension of the film is 3, due to the relatively high thickness of these films compared to the metallic grain size, the grain shape being roughly spherical. As the percolation is approa-
two phenomena conjugate for moving the threshold towards higher metal fraction : 1) the cluster size is increasing, pushing the medium to a 2D behaviour ; 2) the morphology of the samples is such that, up to high metal fractions, each metal grain is surrounded by a layer of the amorphous dielectric matrix (see below) ; the inhomogeneous medium is not therefore truly random, as already emphasized [8].

The morphology of these films was studied by using transmission electron microscopy (TEM) and electron diffraction performed on thinner films deposited under identical conditions onto carbon coated copper grids (Figs. 2 and 3). The diffraction patterns show that for both compounds, the metallic phase is crystallized whereas the dielectric one is amorphous. Below the percolation threshold, both compounds are composed of roughly spherical metallic inclusions embedded

in an amorphous matrix. The metallic cluster mean size is fairly concentration independent (in this dielectric regime): 4-5 nm for Pt and 3-5 nm for Au; but it is increasing with the substrate temperature during the deposition. Around the percolation, the grains tend to become tortuous cluster, the metal and dielectric phases presenting then the same morphology. At the percolation threshold, an infinite cluster is formed throughout the film and a statistical study of its morphology in the framework of scaling laws and fractal theory allows the determination of the

\(^a\)
critical exponents at percolation, the fractal dimension and the percolation correlation length. These results obtained by image treatment, digitalization and binarization will be published elsewhere.

3. Optical properties.

3.1 Optical measurements and dielectric function calculation. — The specular transmittivity (T) and reflectivity (R) of the films were measured under near normal incidence, in the spectral range 300 to 3000 nm using a Cary 17 spectrophotometer. (For Pt-Al_2O_3 see Figs. 4.)

The complex dielectric function \( \tilde{\varepsilon} \) of the films was calculated by solving the implicit system of the two Fresnel's formulae describing R and T as functions of the complex index \( n \), the thickness \( d \) and the wavelength \( \lambda \):

\[
\begin{align*}
R &= f(n, k, d, \lambda) \\
T &= g(n, k, d, \lambda)
\end{align*}
\]

\( \tilde{\varepsilon} = \tilde{n}^2 \) \( \tilde{\varepsilon} = \epsilon_1 + i\epsilon_2 \).

A computer program for a non-linear least square fit with weighted gradient convergence was used [9].

For several films, no solutions to the equation system (1) has been found below 500 nm. The interesting effects appearing at higher wavelength, this lack is however not too dramatic. It is still possible to analyse the reflectivity and transmittivity spectra directly; the conclusions of both types of treatments are usually in reasonable agreement. The results of \( \epsilon_1 \) and \( \epsilon_2 \) are plotted in figures 6 for Au-MgO and figures 5 for Pt-Al_2O_3 and will be discussed in the following.

Fig. 6. — Dielectric function of Au-MgO granular thin films versus wavelength for different Au volume fractions \( q \) : \( 1. q = 0.16 +, 2. q = 0.26 \times, 3. q = 0.28 \triangle, 4. q = 0.31 \square, 5. q = 0.38 \blacksquare \) see also table 1b. Fit using M.G. theory (dashed lines). Fit using BR theory (full lines).

3.2 The effective medium theories fitting the optical dielectric function. — The dielectric function calculated in 3.1 is, in fact, an average effective
value assuming that the composite medium is macroscopically homogeneous. The Maxwell Garnett [1] and Bruggeman [2] Effective Medium Theories (EMT) allow to calculate this effective dielectric function as a function of the volume fraction of the components and their dielectric function, in the quasistatic approximation which can be considered as valid since the optical wavelength is much larger than the size of the particles. A modern derivation expresses the average electric field in the effective homogeneous medium as the volumic average of the fields inside the metallic and the dielectric clusters. The only difference between the two theories lies in the treatment of these two types of clusters: asymmetric in the Maxwell Garnett’s approach, symmetric or self-consistent in the Bruggeman’s one; this is obvious in the formulation:

\[
\text{MG} \frac{\varepsilon_{av} - \varepsilon_m}{L\varepsilon_{av} + (1 - L) \varepsilon_m} = q \frac{\varepsilon_i - \varepsilon_m}{L\varepsilon_i + (1 - L) \varepsilon_m}
\]

\[
\text{BR} \frac{\varepsilon_i - \varepsilon_{av}}{L\varepsilon_i + (1 - L) \varepsilon_{av}} + (1 - q) \frac{\varepsilon_m - \varepsilon_{av}}{L\varepsilon_m + (1 - L) \varepsilon_{av}} = 0
\]

where \( q \) is the metal volume fraction, \( \varepsilon_i \) and \( \varepsilon_m \) the dielectric function of respectively the metal and the dielectric. The shape of the clusters has been introduced in these formulations via the \( L \) parameter, called depolarization factor [9] as it can be directly related to the electrical polarizability of the ellipsoidal clusters assumed to have the same orientation:

\[
\alpha_j = \frac{\varepsilon_i - \varepsilon_m}{3[\varepsilon_i + (\varepsilon_m - \varepsilon_i) L_j]} \quad a, b, c \quad j = a, b, c
\]

where \( 2a, 2b, 2c \) denote the principal axes. In the case of an ellipsoid of revolution (\( b = c \)), the depolarization factor along the principal axes can be expressed versus \( c/a \) ratio (Fig. 7). When the ellipsoid is degenerated into a sphere (\( c/a = 1 \)), we have \( L_x = L_y = L_z = 1/3 \) and the tensor is reduced to a scalar. For randomly oriented ellipsoids with various eccentricity, the polarizability has to be replaced by a scalar average polarizability which cannot be related to an average depolarization factor any more. This remark is of great interest for the interpretation of \( L \) fitted values.

The asymmetric expression of the Maxwell Garnett theory predicts a unique type of behaviour for the medium at all composition: either metallic if the medium is considered as dielectric inclusions in a metallic matrix, or dielectric in the reciprocal case. The self-consistent Bruggeman theory with its symmetrical expression predicts on the contrary a transition between a dielectric and a metallic behaviour as the metal volume fraction \( q \) increases. This threshold occurs at a critical value of \( q_c \), curiously equal to \( L \), i.e. directly linked to the particle shape [10].

On the other hand, the Maxwell Garnett theory predicts a sharp resonance in the average dielectric function, corresponding to the vanishing of the denominator of its explicit expression, whereas the Bruggeman average dielectric function does not diverge and presents only a broadened dumped resonance at a somewhat lower energy. These effects are attributed to the excitation of a collective mode of the conduction electrons at the metallic cluster surface. Another formulation of the same effect is the resonance of an interfacial polarization term of these clusters [12].

We now analyse the dielectric function of the Au-MgO and Pt-Al2O3 thin films in the framework of these two theories.

Fig. 7. — Eigenvalues of the depolarization tensor \((L_x, L_y, L_z)\) as a function of the eccentricity \((c/a)\) of the ellipsoidal inclusion.
of the dielectric function due to the conduction electrons \( (\varepsilon_{\text{c.e.}}) \), via their relaxation time \( \tau \) in the Drude formulation:

\[
\varepsilon_{\text{c.e.}} = P - \omega_p^2 / \omega (\omega + i/\tau).
\]

A crystallite size dependent relaxation time \( (\tau_c) \) is classically introduced [13] by adding a corrective term to the inverse of the relaxation time in the bulk metal:

\[
1/\tau = 1/\tau_0 + v_p/\tau.
\]

This term accounts for diffuse scattering at the surface of the particle of radius \( r \) of the electrons travelling with the Fermi velocity \( (v_p) \). Quantum size effects are negligible in this spectral range.

We have neglected such a relaxation time correction in the case of Pt films for three reasons:

1) The particle sizes in the cermet and in the pure Pt film are not strongly different.

2) The corrective term \( v_p/\tau \) presents a negligible relative value compared to the high value of \( 1/\tau_0 \) in our reference Pt film \((> 0.2 \text{ eV})\).

The relative change in the total \( \varepsilon \) due to this variation in \( \varepsilon_{\text{c.e.}} \) is moreover small since the intraband contribution \( \varepsilon_{\text{in}} \) is not the predominant part to \( \varepsilon \), the interband one \( \varepsilon_{\text{ib}} \) (\( \varepsilon = \varepsilon_{\text{c.e.}} + \varepsilon_{\text{ib}} \)) contributing strongly to \( \varepsilon \).

The same considerations applied to noble metals, and especially our pure Au films, show that the size effect correction on \( \tau \) is important:

1) Due to the large crystallite size difference between pure Au and Au in Au-MgO films \(< 0.1 \text{ eV})\).

2) Due to the low value of \( 1/\tau_0 \) in our pure Au films.

3) Due to the absence of an interband transition contribution in Au beyond 600 nm [3].

Figure 9 shows the size dependent relaxation time \( h/\tau_z \) for Au versus the particle radius. The \( h/\tau_z \) value corresponding to the mean cluster size in Au-MgO films (3 to 5 nm) is about 0.6 eV. We have tried an other evaluation of \( h/\tau_z \) by fitting the resonance in \( \varepsilon \) average of Au-MgO films using BR theory, the \( h/\tau_z \) being an extra adjustable parameter (as pointed out before, this resonance is very sensitive to the conduction electron parameters). The scattering of the fitted parameters is very high, but the mean value, 0.62 eV, is in very good agreement with the value deduced from the direct size observations.

3.4 AVERAGE DIELECTRIC FUNCTION OF Au-MgO AND Pt-Al_2O_3 : RESULTS, FIT, DISCUSSION. — As already pointed out for the electrical conductivity, the complex dielectric function of all the five Au-MgO samples \((d_{\text{Au}} < 0.41)\) exhibits a dielectric behaviour (see Figs. 4 : \( \varepsilon_1 \) is positive and \( \varepsilon_2 \) is low in the infrared), while the cross-over between a dielectric and a metallic \((\varepsilon_1 \) negative and \( \varepsilon_2 \) increasing in the infrared) optical behaviour is observed in Pt-Al_2O_3 films between 0.43 and 0.53 Pt volume fraction (see Figs. 5).

The dielectric anomaly or surface plasmon resonance is clearly observed in all Au-MgO films between 0.43 and 0.53 Pt volume fraction (see Fig. 5). At high Au volume fraction. A very smooth absorption band is observed around 500 nm only in the first Pt-Al_2O_3 film \((q = 0.18)\). This effect as well as the difference between the Au-MgO and Pt-Al_2O_3 behaviours can be at least qualitatively explained in the framework of the M.G. theory. It has been demonstrated that the M.G. function representation in the complex plane [14, 15] is constituted by two families of orthogonal circles, converging at a unique point corresponding to the function pole. The corresponding curves plotted for Pt and Au with various relaxation times, show that (Fig. 10):

— The Au curve distance from the pole increases with the inverse of the relaxation time and the resonance is consequently dumped.

— The Pt curve remains far from the pole and its nearest point is shifted towards short wavelengths \( (0.42 \text{ nm} \) instead of \( 0.55 \text{ nm} \) for gold). The resonance is quite inexistant and equally shifted.
Fig. 10. — Representation in the complex plane, of the dielectric function of Au-MgO and Pt-Al_2O_3 granular compounds calculated using M.G. theory with a metal volume fraction \( q = 0.30 \). On the axis are plotted the real and imaginary parts of the metal (Au or Pt) dielectric function. The (full and dashed lines) circles represent the M.G. calculated average dielectric function (real and imaginary parts) of the granular media. The intersections of the double full lines with the circles give, versus the wavelength, the MG average dielectric function of Pt-Al_2O_3 compounds and Au-Al_2O_3 compounds (for two relaxation time values).

The results of the fit of the experimental average dielectric function using the M.G. and the BR theories are plotted on figures 5 and 6. The fitted parameters \( q \) (metallic volume fraction) and \( L \) (depolarization factor) are given in tables I. In the case of Pt-Al_2O_3, the fit has been performed either on \( \epsilon \) (complex) or \( R \) and \( T \) experimental values. It is evident on figures 5 and 6 that the M.G. theory is not adequate to account for the dielectric function of these films. The fitting procedure leads to diverging values of the depolarization factor \( L \) (towards 1 or 0) while the fitted \( q \) values remain far from the experimental ones. In contrast, the BR theory gives a fairly good account of the experimental results. It seems however more difficult to fit both the dielectric anomaly and the infrared behaviour in Au-MgO films than the smooth variations of the dielectric function over the whole spectral range in Pt-Al_2O_3 films. There is no significant difference between the fit on \( \epsilon \) (\( \epsilon_1 \) and \( \epsilon_2 \)) (Fig. 5) and on \( R \) and \( T \) (Fig. 4) (for Pt-Al_2O_3 films) except near the percolation where the fit on \( \epsilon \) is worse due to the strong variations of \( \epsilon_1 \) compared to \( R \) and \( T \) at \( q_c \). A few remarks can explain these behaviours and the fit accuracy:

1) The M.G. theory which predicts a very sharp resonance at the surface plasmon frequency is evidently not adequate for these films (even for Au-MgO ones, where a resonance is observed). Moreover, even at relatively high \( q \) values, M.G. always predicts very low infrared \( \epsilon_2 \) values in the dielectric regime in contrast to our results.

2) In the M.G. and BR formulations, when the metallic inclusion (\( \epsilon_1 \)) dielectric function is large compared to the dielectric function of the average medium (\( \epsilon \)) and the dielectric matrix (\( \epsilon_{in} \)), the \( \epsilon_1 \) term can be eliminated and the medium behaves now quite independently of the nature of the metallic inclusions. This situation is reached in Pt-Al_2O_3 around 500 nm while only around 1 000 nm in Au-MgO, due to the quasi free electron behaviour of Au in the near infrared and the presence of interband transitions in Pt inducing a high near infrared dielectric function. This qualitative consideration explains the important influence of the relaxation time pointed out above in the dielectric function variations of Au-MgO films up to 1 \( \mu \)m and its negligible influence in the case of Pt-Al_2O_3.

3) The last remark is valid except near the percolation threshold where the BR theory predicts a predominance of plasmon resonance over all wavelength (up to \( \lambda \to \infty \))[10]. In fact in this critical fraction domain both \( q \) and \( L \) fitted values are completely inadequate, whereas they were in relatively good agreement with the experimental characteristics elsewhere (especially \( L \), close to 1/3 which is probably the only significant value for randomly oriented particles). In this region we will show in another paper that the BR theory fits, in fact, the quantity \( q-L \), the \( L \) depolarizing factor losing near \( q_c \) its significance related to the inclusion shape, as the random isolated clusters are replaced by an infinite cluster.

4. Conclusion.

We have presented in detail a comparative study of the structural, electrical and optical properties of Au-MgO and Pt-Al_2O_3 granular films. As predicted by the effective medium theories, we have distinguished two main phenomena in the optical properties. First, the dielectric anomaly or surface plasmon resonance which is essentially a local effect related to a resonance in the metallic clusters (depending on their nature, shape, size). We have pointed out the key role of the nature of the metal (noble or transition) on this resonance, both in the theories and in the experimental results. The influence of the size-dependent relaxation time of the conduction electrons has been discussed in Au-MgO films. Second, the optical crossover accompanying the electrical percolation and the morphological percolation at about the same critical metal volume fraction, which is essentially a structural effect related to the disorder rather than to the nature of the metallic clusters. We have shown that the experimental value of \( q_c \) is higher than the value predicted by calculations for 3D systems; this is due to the particular morphology of the films. It is well known that none of the effective medium theories gives a good account of the dielectric function around the percolation. This is obvious for M.G. which does not predict any percolation phenomenon. We have remarked that, although leading to inadequate \( q \) and \( L \) parameters near \( q_c \), the BR theory correctly gives the \( q-L \) quantity, \( L \) being no more related to the mean shape of the clusters but to the percolation critical volume fraction. This point will be developed in a further publication.

Eventually, we have shown that the near infrared
behaviour of Au-MgO films is more dependent on the metal dielectric function than that of Pt-Al₂O₃ films as the transition metal dielectric function is 3 or 4 times larger than the noble metal one, due to the contribution of interband transitions in the low energy range.

Acknowledgments.

We wish to thank C. Sella (CNRS-Bellevue) and D. Mazieres (CEN-Grenoble) for sample preparation and M. L. Thèye for helpful comments and suggestions.
