Laboratoire de Physique des Solides, C.N.R.S., 1, place Aristide Briand, 92190 Meudon-Bellevue, France

Abstract: The infrared spectra of chlorinated and hydrogenated amorphous silicon have been measured. In addition to the hydrogen induced bands at 2110, 1990, 885, 840 and 640 cm\(^{-1}\), we observe two new modes at 545 cm\(^{-1}\) (Si-C\(_1\) stretching) and 500 cm\(^{-1}\) (Si TO modes induced by chlorine). Observation of the 545 cm\(^{-1}\) band proves that chlorine acts as a dangling bond terminator. Upon annealing, some of the Si-C\(_1\) groups transform into SiCl\(_4\) molecules (SiCl\(_4\) stretching at 615 cm\(^{-1}\)). A good agreement is found between the total amount of chlorine determined by electron microprobe analysis and the value estimated from the integrated strength of the Si-C\(_1\) stretching mode.

Introduction:

A great deal of attention has been given in the past to hydrogenated amorphous silicon because of its potential application as a solar cell material \(^{(1)}\). More recently, SHIMADA et al. established that fluorine is able to compensate the dangling bonds as hydrogen does \(^{(3)}\). Moreover, MADAN has shown that addition of fluorine in phosphorus doped materials results in a higher doping efficiency and a lower resistivity never achieved in hydrogenated amorphous silicon \(^{(4)}\).

Other halogens can be imagined as dangling bond terminators. However, nothing has been reported until now about the role of chlorine in an amorphous silicon matrix. In this paper, we report infrared absorption measurements in chlorinated and hydrogenated amorphous silicon (a-Si:H, Cl) and the first observation of chlorine related bands. We discuss their origin and infer that chlorine acts as a dangling bond terminator. The thermal stability of hydrogen and chlorine was investigated from annealing experiments.

Preparation of a-Si:H, Cl films:

Samples with thickness of 1um were prepared on crystalline silicon wafers by glow discharge of a silicon tetrachloride (SiCl\(_4\)) and hydrogen mixture. The substrates were held at about 280°C. The power level was 0.2 watt/cm\(^{2}\) and the growth rate 3 Å/s. Our films contained 6 to 7% atomic chlorine as determined from electron microprobe analysis and 5% atomic bounded hydrogen as we shall see further. More information on the preparation conditions and properties of the films will be published elsewhere \(^{(5)}\).

Absorption spectra:

Figure 1 shows a typical infrared spectrum of a a-Si:H,Cl film in the range 4000–200cm\(^{-1}\) recorded with a PERKIN-ELMER 683 spectrophotometer. The hydrogen induced bands are identified by comparison with purely hydrogenated amorphous silicon \(^{(6,7)}\):

Fig. 1 - Typical infrared spectrum of a a-Si:H,Cl sample.
they are successively attributed to stretching modes of \(\text{SiH}_2\)_n and \(\text{SiH}_2\) groups (2110 cm\(^{-1}\)), stretching modes of \(\text{SiH}\) groups (1990 cm\(^{-1}\)), bending modes of \(\text{SiH}_2\) (885 cm\(^{-1}\)) and \(\text{SiH}_2\) (840 cm\(^{-1}\)) and wagging-rocking modes of \(\text{SiH}\) and \(\text{SiH}_2\) species (640 cm\(^{-1}\)). The bands at 740 cm\(^{-1}\) and 795 cm\(^{-1}\) are not reported in a-\(\text{Si:H}\) literature. Their origin is not clearly established.

Two modes appear at low energy. The main band, located at 545 cm\(^{-1}\), has not been reported until now. We rule out the possibility of chlorosilane molecules \(\text{SiCl}_n\text{H}_{4-n}\) (1\(\leq n\leq 4\)) embedded in the matrix because either the \(\text{Si-Cl}\) stretching mode frequencies of these molecules are too far from this value or their \(\text{Si-H}\) stretching modes are not visible in our infrared spectra. In figure 2, we present the \(\text{Si-Cl}\) stretching frequency dependences of a number of \(\text{SiCl}_n\text{X}_{4-n}\) molecules with the SANDERSON's electronegativity sum of \(\text{X}_n\)-atoms \((\text{X}=\text{F},\text{I},\text{Br},\text{H})\). These frequencies cover a range from 621 cm\(^{-1}\) \((\text{SiCl}_4)\) to 498 cm\(^{-1}\) \((\text{SiCl}_3\text{H})\). The arrows indicate the electronegativity of various configurations involving one, two or three chlorine atoms bonded to the same silicon atom. We clearly see that the 545 cm\(^{-1}\) frequency falls within the corresponding range. This result suggests that the 545 cm\(^{-1}\) band in related to a \(\text{Si-Cl}\) stretching vibrational mode with a chlorine atom forming a single bond with silicon. This is the first observation of chlorine acting as a dangling bond terminator in a hydrogenated amorphous silicon matrix.

**Fig. 2** - Variation of the \(\text{Si-Cl}\) stretching mode frequency versus the electronegativity sum of substituted elements in various chlorosilane molecules.

The band at 500 cm\(^{-1}\) appears as a tail of the main band at 545 cm\(^{-1}\) (see insert of Fig.1). Without discarding the presence of some \(\text{Si-Cl}\) symmetric stretching mode due to a different configuration, we attribute this band to a TO optical phonon of the amorphous silicon matrix. Because of its large electronegativity, chlorine induces a charge transfer in its neighborhood. As a consequence, infrared inactive mode of non-polar silicon becomes activated in chlorinated amorphous silicon.

**Annealing experiments**

Isochronal annealings have been performed on a series of samples. Films were heated for 45 minutes in a purified \(\text{H}_2\) flow. The hydrogen bands remain constant up to 320°C and then decreases rapidly (Fig. 3). The behaviour of the 2110 cm\(^{-1}\) stretching mode with annealing is quite different from that of the 885 cm\(^{-1}\) bending modes of \(\text{SiH}_2\) groups. Hence, this band is partly due to species other than \(\text{SiH}_2\). The \(\text{SiH}\) stretching frequency is known to depend on the electronegativity of substituted species. Following LUCOVSKY \(\text{77}\), we can estimate that the \(\text{SiH}\) stretching frequency in \(\text{SiHCl}\) and \(\text{SiH}_2\text{Cl}\) configurations will be respectively 2100 and 2140 cm\(^{-1}\). Consequently, we think that these species probably contribute to the 2110 cm\(^{-1}\) absorption band.

The \(\text{Si-Cl}\) stretching band decreases also above 320°C but relatively more slowly than most of hydrogen induced bands. An interesting feature of this band is shown in the insert. Its corresponding frequency continuously shifts from 545 cm\(^{-1}\) to 578 cm\(^{-1}\) as the annealing temperature increases from 260 to 600°C. This effect suggests a change in the configuration involved in the \(\text{Si-Cl}\) stretching mode. Such changes have been observed in purely a :\(\text{Si-H}\) \(\text{87}\) and interpreted as the result of \(\text{Si-H}\) bonds in a cluster of four, pointing towards the equivalent of a crystalline silicon vacancy. Because of the large size of chlorine atoms, we think that such clusters are unlikely. Figure 2 shows that the stretching mode frequency increases as
silicon is replaced by hydrogen or chlorine atoms in the various possible configurations around a given silicon atom. We suggest that in unannealed samples, the dominant configurations are SiHCl or (and) Si-H Cl. As the temperature increases, hydrogen and chlorine are released from such configurations which would favor the formation of SiCl₂ and SiCl₃ types of configurations. Such a view is supported by the following experimental fact. Above 400°C, a new band located at 615 cm⁻¹ appears in our infrared spectra. It is interpreted as the asymmetric Si-Cl stretching mode of SiCl₄ molecules formed in the matrix during annealing. Formation of SiF₄ molecules have also been observed in annealing experiments of a-Si:H,F samples [27].

Bounded chlorine and hydrogen concentrations:

By using an oscillator strength value of 16 cm²/mmole. bond deduced from published absorption data of various chlorosilane gases and local field corrections given by BRODSKY [10], we found 8% atomic bounded chlorine from the integrated Si-Cl absorption band at 545 cm⁻¹. This is in good agreement with the 6-7% determined from electron microprobe analysis. The concentration of bounded hydrogen has been calculated from the integrated absorption of the Si-H wagging band at 540 cm⁻¹ [6-7]. A value of 5% atomic has been found.

Conclusions:

From the observation of the Si-Cl stretching mode in i.r. absorption, we have established that chlorine is able to compensate the dangling bonds as fluorine and hydrogen do.
