Résumé - Sur deux nuances de céramiques de type SiYAlON, obtenues par frittage naturel, il est montré l'intérêt, pour améliorer la résistance au fluage, de traitements thermiques en lit de poudre sous atmosphère d'azote.

Abstract - For two batches of pressureless sintered SiYAlON ceramics, it is demonstrated that the creep resistance may be improved by using powder bed heat treatments in nitrogen atmosphere.

I - INTRODUCTION

It is now well established that the high temperature behaviour of nitrogen ceramics is linked to the properties of the residual intergranular phase, i.e., to the nature and quantity of densification aids and to the metallic impurities in the raw materials. This intergranular phase may be modified by post-sintering heat treatment in oxidizing or neutral atmospheres /1/. These possibilities have been illustrated by the study of the creep behaviour of two SiYAlON materials with the same nominal composition, but with a different impurity content (Ca, Fe).

II - MATERIALS

Two batches of samples (N3 and N5) were prepared from silicon, aluminium and yttria powders. The nominal composition is the same, except for the purity of the silicon powder (Table 1). The powders are mixed in alcohol, dried, then nitrided during a 70 hour thermal cycle. The reaction kinetics are controlled by nitrogen consumption /2/. The bricks are crushed and finely ground ($\phi < 2 \mu\text{m}$). After shaping, the samples are densified by pressureless sintering at 1700°C in nitrogen to 95% theoretical density.

Powder	PURITY wt %		
	Ca	Fe	Al
Si(N3)	0,02 - 0,14	0,48 - 0,58	0,02 - 0,15
Si(N5)	n.d. - 0,02	0,35 - 0,48	0,07 - 0,08
Y ₂ O ₃	n.d.	50 ppm	n.d.
Al	43 ppm	2000 ppm	

Table 1 : Impurity content of the powders.

i - As sintered materials consist in $B'Si_{5.6}Al_{0.4}O_{0.4}N_{7.6}$ as the major phase, with a small amount of yttrium silicate ($B'Y_2Si_2O_7$) and a rather large quantity of glassy phase (Fig. 1). No yttrium aluminium garnet has been detected either in N_3 or N_5 materials.

ii - After heat-treatment in air (48 h - 1350°C), microanalysis (E.D.A.X.) reveals a migration of calcium and yttrium which concentrate in the oxide scale at the external interface. T.E.M. micrographs show a partial microcrystallization of the glassy phase pockets (Fig. 2).

iii - Heat-treatments have also been performed in a powder bed. The bars ($4 \times 4 \times 25$ mm³) are embedded in silicon nitride powder (purity 99.9%) and treated in nitrogen for 100 hours at temperatures between 1150 and 1300°C. A complete recrystallization of the glassy phase is evidenced by lack of any alteration under the electron beam during TEM investigation (fig. 3). X-Ray diffraction patterns show an increase in $Y_2Si_2O_7$ and the appearance of $AlYO_3$ and of new phases which have not yet been identified. No outward diffusion of yttrium was detected by EDAX microanalyses of the sample surface.

III - CREEP

The 3-point bending creep tests in air are performed between 1100 and 1250°C at stresses ranging from 70 to 165 MPa. The stress and strain at the outermost fibre are calculated under elastic theory assumptions. This approximation is justified by the low value of the measured deflection and the newtonian behaviour of the flow in the stationary stage /3/. Typical creep curves are shown in figure 4. After a rapid decrease at the beginning, the creep rate continues to diminish slowly. A true steady state is reached only after several hundred hours. A tertiary creep has never been observed under our experimental conditions.

i - Creep of the as-sintered N_2 material has been studied using the phenomenological relation $\dot{\epsilon} = A(S) \sigma^n \exp - E/RT$ where $\dot{\epsilon}$ is the creep rate at the outer tensile fibre, σ the maximum tensile stress, n the stress exponent, E the apparent activation energy, R the Boltzmann constant, T the absolute temperature and $A(S)$ a factor depending on the microstructure.

Determination of n , through stress-steps experiments, shows a linear and reversible variation of $\ln \dot{\epsilon}$ versus $\ln \sigma$ for times greater than 340 hours (fig. 5). During the long preceeding period when the creep rate is slowly decreasing, the microstructure changes due to the oxidation and the decrease in quantity of the intergranular glassy

phase (fig. 6). This oxidation leads to an outward migration of yttrium and calcium [4]. Studies of the oxidation behaviour have allowed us to link the onset of the stationary stage with an intergranular oxidation completed in the bulk of the samples. At this stage, the evolution of the microstructure is achieved ; the contribution of the viscoelastic effects to the creep rate becomes negligible ; the only remaining mechanism is a diffusional one ($n = 1$, $E = 780$ kJ/mol). This mechanism corresponds to a solution-migration-precipitation process induced by chemical potential gradients which arise from the buttressing of adjacent grains on ledges along grain-boundaries.

ii - N_5 material shows a similar behaviour with a better resistance (fig. 4). The steady stage is reached more rapidly. The lower calcium and iron contents increase the refractoriness of the glassy phase.

iii - For N_3 pre-oxidized samples also, the stationary stage is observed for shorter pre times than in as-sintered N_3 samples, but the steady creep rate is higher (fig. 4). After creep test, no noticeable microstructural changes have been observed, which means that the microstructure has been stabilized by the oxidation treatment. A consequence of the partial microcrystallization of the glassy phase pockets may be that the solution-migration-precipitation process can now occur at buttressing points between crystallites. This possibility of matter flow between silicate crystallites through the oxidized residual glassy phase might explain a higher value for the creep rate in the steady-state creep.

Fig. 6 : T.E.M. micrograph of N₃-sample after creep.

i.v - After treatment in a powder bed at 1150°C, the behaviour is similar to that of the as-sintered material, but improves with increasing heat treatment temperature. In the case of a sample heat treated at 1250°C, the steady state creep rate is lower and the strain is three times less than in the case of the as-sintered material, all else being equal. This improvement is ascribed to the crystallization leading to the almost complete disappearance of the vitreous phase. The powder bed protects the samples from any decomposition and for reaction with oxygen traces in the atmosphere.

IV - CONCLUSION

This study demonstrates that the difference in behaviour between the two SiYALON materials, N3 and N5, of the same nominal composition, is related to their different calcium impurity contents ; iron does not seem to play any role. Thermal treatments either in oxidizing or neutral atmospheres, lead to the crystallization, more or less complete, of the secondary glassy phase. In oxidizing environments, surface pitting limits the duration of the treatment, whereas in the case of the powder bed technique, the samples are protected from surface degradation and reach the stable thermodynamical state characterized by the elimination of the transient glassy phase.

For this SiYALON ceramic, heat treatments in nitrogen using a powder bed induce a marked improvement in the creep resistance.
