HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
VUV SOURCE FROM PULSED-LASER GENERATED PLASMA

P. LAPORTE, N. DAMANY and H. DAMANY

Equipe de Spectroscopie, Laboratoire de Spectrométrie Ionique et Moléculaire (CNRS UA-171, Greco Celphyla) Universités de Saint-Etienne et Lyon-I, 158 bis, Cours Fauriel, F-42023 Saint-Etienne Cedex, France

We describe a pulsed vacuum ultraviolet (VUV) source consisting of a plasma created by focusing a NdYAG laser beam into rare gases under moderate pressure, and we report on spectral and time properties of that source. Main features are: continuum emission in a large spectral range, with only few lines superimposed, good time characteristics of the pulses, stability, cleanliness, and relatively high repetition rate (20 Hz).

In the experiments presented here, the plasma is fired by focusing into neon, argon or krypton, under pressure 0.5 to 5 bar, the residual part (infrared + green) of a Q-switched NdYAG laser (YS 561-20 from Quantel). The available energy per 10 ns pulse is typically 330 mJ. The emission spectrum is observed at the exit slit of a VUV grating monochromator ASM 100 from Jobin-Yvon, and measured with the help of a MgF₂ windowed photomultiplier equipped with CsI or CsTe photocathode, or with a NO ionization chamber.

![Fig 1: Emission spectrum from argon plasma, argon pressure: 2 bar: 110 nm < \(\lambda\) < 150 nm : CsI photocathode 150 nm < \(\lambda\) < 300 nm : CsTe photocathode. Non referenced lines are principally from Ar II](image-url)
The emission consists essentially in a continuum extending in the whole investigated spectral range (115-300 nm) except for the case of Kr, for which the cut-off at 128 nm is due to the absorption by the broadened first resonance line. A few broadened emission lines are superimposed onto the continuum, due to the singly ionized gas (especially in the case of argon) or, possibly, to neutral impurities (Fig. 1).

Emission intensity, corrected for detector response, reveals a maximum located near 175 nm for the three gases; so plasma temperature is estimated to be 16500 ± 500 K.

Dependence of emission intensity versus pressure or excitation energy is illustrated in Figs. 2 and 3.

![Fig. 2 Intensity of laser plasma emission vs gas pressure, laser pulse energy 330 mJ.](image1)

![Fig. 3 Intensity of laser plasma emission vs laser energy at an argon pressure of 1.2 bar.](image2)

The maximum number of photons available at the exit slit of the monochromator around 175 nm (maximum of the emission) when firing with a 20 Hz, 300 mJ YAG laser is ≈ 5×10^9 photons nm⁻¹ s⁻¹ with argon, and 10⁹ photons nm⁻¹ s⁻¹ with krypton.

Fig. 4 gives typical curves of time behavior of the continuum emission.

Full time widths at half maximum (FWHM) are ≈ 20 ns, 30 ns and 40 ns for neon, argon and krypton respectively, including the laser time-width contribution.
Advent of multikilohertz lasers (YAG, Copper...) of enough peak intensity is one possibility of improving the average intensity of such a source.
