RESUME - Nous présentons dans cet article la production d'impulsions de 20 fs très énergétiques (qq microjoules). Le spectre d'une impulsion de 80 fs est élargi par automodulation de phase dans une fibre optique monomode. L'impulsion est amplifiée dans un amplificateur à multipassages en utilisant un mélange de colorant pour augmenter la bande d'amplification et ensuite compressée.

ABSTRACT - We describe the production of 20 fs, a few microjoules pulses using amplification in a multipass amplifier and compression of 80 fs pulses spectrally broadened by self-phase modulation in a monomode optical fiber. To improve the amplification bandwidth we have used a mixture of two dyes.

With the development of mode-locked lasers, the temporal resolution of physical phenomena kinetics measurements is limited by the laser pulse width. The compression of optical pulses spectrally broadened by self-phase modulation /1/ is the method generally used to obtain the shortest pulses /2/. Recently, Fork et al. have reported the compression of optical pulses to six femtoseconds /3/. But unfortunately, the single mode fibers used limit the input peak power to a few hundred kilowatts. Moreover, the study of non-linear interactions induced by optical pulses needs high energy levels. These compressed pulses can not be used as a pump in such experiments. At this time, the temporal resolution is limited around 50 fs /4/ by the duration of the high peak power amplified pulses produced by the classical system containing a colliding pulse mode locked laser (CPM) and an amplifier. We report here the generation of 20 fs pulses with energy of a few microjoules by large bandwidth amplification of optical pulses spectrally broadened by self-phase modulation in a single mode fiber.

In our experiment, we have used optical pulses produced by a CPM laser and amplified with a 3 ns Nd:Yag laser at a 10 Hz repetition rate to energies of about 1mJ. The pulses duration is 80 fs and their spectrum is centered at 615 nm. A fraction of the pulse energy is coupled with a 20 x microscope objective into a 15 mm long single mode fiber with a 4 μ m core diameter (Fig. 1). We estimate the intensity in the fiber close to 50 kW.

Figure 1 : Experimental set-up

A typical pulse spectrum at the output of the fiber is shown in Fig. 2. One can see an asymmetrical shift of the spectrum towards the shorter wavelengths. At the fiber output, the pulse has been lengthened by group velocity dispersion and its duration is estimated to about 1 ps. The beam is then collimated with a 50 x microscope objective. To increase the energy, we amplify the pulses before compression. In fact, long pulses make the amplification more efficient and limit non linear effects in this process. Furthermore, recent experiments using solid state amplifiers and linearly chirped pulses /5/ have shown that the phase relation between the frequency components is conserved after the amplification allowing good compression ratios.

Figure 2 : Broadened pulse spectrum at the output of the fiber. The input pulse peak power is estimated from the spectrum FWHM at 50 kW. The input spectrum is given as a comparison (hatched curve).

Figure 3 : Amplified pulse spectrum using a DCM ($2 \cdot 10^{-5}$ M/l) and Rhodamine 610 ($2 \cdot 10^{-5}$ M/l) mixture.

We use a multipass amplifier /6/ to improve the gain efficiency. The pulse passes six times through a 5 mm dye cell pumped by a 20 mJ, 3 ns pulse produced by a Nd:Yag laser (Fig. 1). The main problem is the choice of the amplifier dye. This dye must have a good efficiency in a large spectral band centered on the laser wavelength. In fact, the compressed pulse duration will be limited by the possibility of amplifying a large spectral band, where the chirp of the pulse is linear. We have studied several dyes to amplify the large output spectrum issued from the fiber and we have found that the amplification bandwidth was generally shorter than the tuning curve of the dye as obtained in tunable dye laser. So we decided to mix two dyes to center and increase the bandwidth of the amplified spectrum. The problem is that the fluorescence of the first dye must not be absorbed by the second dye. Two dyes : Rhodamine 610 and DCM (4 Dicyanomethylene-2-methyl-6p-dimethylaminostyryl-4H-pyran) were used because they have complementary spectral bandwidths and because the DCM absorption maximum (481 nm) is at a lower wavelength than the Rhodamine 610 fluorescence maximum (588 nm). Dye concentrations were approximately $2 \cdot 10^{-5}$ M/l for the DCM and $2 \cdot 10^{-5}$ M/l for the Rhodamine 610 (dissolved in Methanol). Fig. 3 shows a typical amplified spectrum with a mixture of Rhodamine 610 and DCM. The full width at half maximum (FWHM) is 30 nm. Because it is difficult to measure the energy of pulses at a low repetition rate (10 Hz), we have estimated the amplified pulses energy to about a few microjoules by measuring the efficiency gain of our multipass amplifier with this dyes mixture.

The amplified chirped pulses are then compressed with a sequence of four high index refraction prisms /7/ given a very good transmission ratio. The compressed optical pulses are measured using a single shot correlator /8/. With an optical multichannel analyzer (O.M.A.), we record the spatial profile of the second harmonic beam produced when two expanded beams cross in a 0.3 mm non-linear crystal (KDP). This system gives a real time visual-

lization of the pulse autocorrelation and then allows us a precise adjustment of the prisms compressor. We regularly obtain single-shot autocorrelation functions, which correspond to pulses FWHM under 25 fs (assuming a hyperbolic secant pulse shape). The shortest pulses obtained (Fig. 4) have a FWHM of 20 fs. The corresponding spectral width as seen from Fig. 3 is 30 nm. For this spectral width (and a hyperbolic secant pulse shape), a minimum pulse width of 13 fs is possible, indicating that our pulses are close to the Fourier transform limit. One can see that the autocorrelation function presents wings. We think, that it corresponds to a non linear chirp which is not compensated by our compressor system. In fact, if the sequence of four high index refraction prisms is very compact and have a good transmission ratio, it presents a large negative cubic dispersion, leading to compressed pulses which present an oscillatory trailing edge /9/. We are presently studying a compressor containing two high transmission gratings and two prisms to compensate the cubic dispersion and obtain high energy pulses without trailing edge.

Figure 4 : Single shot autocorrelation of a 20 fs (50 MW) amplified and compressed pulse.

The stability of the compressed pulses directly depends on the spectral broadening in the optical fiber. By averaging twenty consecutive autocorrelation traces, we observe a broadening from 20 to 24 fs. This small broadening indicates a good shot to shot stability. Moreover we have also measured the beam divergence using a long focal lens (2 m) and a detector array. Results show the 20 fs pulses to be 1.1 times diffraction limited. Therefore it seems that the amplifier does not affect the spatial beam profile. This beam once focused could produce intensity in the range of 10^{15} W/cm². To prove the possibility of using these amplified ultrashort pulses in spectroscopic experiments, we have focused the beam in a 1 mm cell of water using a 35 mm lens. We then observed a spectral continuum extending from UV to IR with a very good pump depletion. The stability of the continuum was comparable to the one obtained using the initial 80 fs pulses. At this time, the study of several ultrafast effects is limited by the pump pulse duration. We think that the use of these ultrashort pulses can lead to a more comprehension of these effects.

In this paper, we present the generation of high energy 20 fs pulses. The broad spectrum produced in a single mode fiber by self-phase modulation is amplified in a multipass amplifier using a mixture of two dyes. The pulse energy is sufficient to create non-linear effects such as a continuum and so decrease our temporal resolution in spectroscopic experiments under 20 fs. To our knowledge these are the shortest amplified pulses produced at this time.
