Résumé. — Nous montrons que l’élargissement sous l’effet de la pression de la largeur
$2 \sqrt{4 V^2 + (1/\tau)^2}$ d’un signal d’anticroisement (où $V$ est le couplage entre les deux niveaux qui
s’anticroisent et $\tau$ l’inverse de leur durée de vie) n’est pas dû seulement à l’accroissement de $\tau$ sous
l’effet des collisions. Nous montrons que la largeur du signal est donnée par la formule
$2 \sqrt{4 V^2 \delta \langle T / \tau \rangle + (1/\tau)^2}$, où $\delta \langle T / \tau \rangle$ est le rapport des temps de relaxation effectifs de la cohérence et
des populations des deux niveaux.

Abstract. — We show that the pressure broadening of the width $2 \sqrt{4 V^2 + (1/\tau)^2}$ of an anti-
crossing signal (where $V$ is the coupling between the anticrossing levels and $\tau$ the reciprocal of their
lifetime) is caused by more than just the increase of $\tau$ by collisions. We find that the linewidth is given
by $2 \sqrt{4 V^2 \delta \langle T / \tau \rangle + (1/\tau)^2}$, where $\delta \langle T / \tau \rangle$ is the ratio of the effective relaxation times of the coherences
to the populations of the anticrossing levels.

1. Introduction. — The anticrossing phenomenon occurs whenever two levels $|a\rangle$ and $|b\rangle$, with
unperturbed energies $E_a$ and $E_b$, of an atom or a
molecule are brought into near coincidence by applying a magnetic field, provided that they are
coupled by some interaction $V = \langle a | \mathcal{U} | b \rangle$. In the vicinity of the crossing point, the eigenvalues $E_a$
and $E_b$ of the total Hamiltonian repel one other and
and the associated eigenfunctions $|+\rangle$ and $|-\rangle$ are
mixtures $|a\rangle$ and $|b\rangle$. This produces an equalization
of the populations of $|a\rangle$ and $|b\rangle$ at the avoided
crossing point if some steady state excitation mech-
anism produces a difference between the populations of
$|a\rangle$ and $|b\rangle$. This resonant-like variation of
population may be observed by monitoring separately
the intensity (and/or polarization) of the light emitted
by $|a\rangle$ and $|b\rangle$. This phenomenon was observed for the first time on the sublevels of the $2^1P$ manifold
of Li [1]. The coupling was due to the hyperfine
interaction. Since then, several other experiments have
been carried out in which $\mathcal{U}$ was due to an
electric field connecting two opposite parity levels [2],
and more recently to a fine or hyperfine interaction
connecting singlet and triplet levels of helium-like
systems [3]. This last kind of experiment has led to the
relaxation studies which follow.

We would like to mention from the onset that experiments of magnetic or electric resonance can be
considered as anticrossing experiments in the space
of atom + quantized radiofrequency field [4] so that
effects analogous to the one we study here do exist in
resonance experiments. One aspect of this similarity
is studied in the third paragraph.

The usual calculation of the anticrossing signal for
steady state excitation, based on the solution of the
following rate equation for the density matrix

$$i \frac{d\rho}{dt} = 0 = \frac{1}{\hbar} (\mathcal{K}_0 + \mathcal{U}, \rho) + iN + \frac{d\rho}{dt}_{\text{rad}}$$

(1)

with

$$\mathcal{K}_0 |a\rangle = E_a |a\rangle, \quad \mathcal{K}_0 |b\rangle = E_b |b\rangle, \quad \langle a | \mathcal{U} | a \rangle = \langle b | \mathcal{U} | b \rangle = 0, \quad \langle a | \mathcal{U} | b \rangle = V, \quad \text{is straightforward. In the simplest case in which two levels}
\text{of same radiative lifetime } 1/\Gamma \text{are excited}
incoherently with rates } n_a \text{ and } n_b \text{ one finds that the}
\text{steady state population of } |a\rangle \text{ is}
$$

$$\rho_a = \frac{n_a}{\Gamma} - \frac{2 |V|^2}{\Gamma (E_a - E_b)^2 + 4 |V|^2 + (h\Gamma)^2} n_a - n_b$$

(2)

(and the symmetric formula for $\rho_b$). This produces,
as a function of $(E_a - E_b)$, a Lorentzian signal of
width at half maximum

$$\Delta E = 2 \sqrt{4 |V|^2 + (h\Gamma)^2}.$$

(3)
We have performed experiments on singlet-triplet anticrossings of $^4$He [3]. In this case $V$, the spin-orbit coupling, is roughly 100 times larger than the radiative decay term $\hbar \Gamma$, so that the influence of $\hbar \Gamma$ in (3) on the linewidth is only $10^{-4}$. When one increases the pressure to a few times $10^{-1}$ torr, $\Gamma$ is shortened by collisions by a factor of two or three [5] which, according to formula (3), implies a negligible broadening of the anticrossing curve. In fact, we have found experimentally that the width was roughly doubled. The purpose of this letter is to give the explanation of this phenomenon.

2. Theory. — At high pressure, when the interatomic collisions do play a role, eq. (1), restricted to the two anticrossing levels $|a\rangle$ and $|b\rangle$, is no longer sufficient. $|a\rangle$ and $|b\rangle$ are two particular Zeeman sublevels, amid two Zeeman sets $|a'\rangle$, $|a''\rangle$ ... and $|b'\rangle$, $|b''\rangle$ ... of two levels $a$ and $b$. The collisions produce transfers between Zeeman sublevels of a same level, as well as quenching transfers to other levels. One takes this into account by replacing eq. (1) by:

$$\frac{d\rho}{dt} = \frac{1}{\hbar} \left( \mathcal{H}_0 + \mathcal{U}, \rho \right) + iN + \frac{d\rho}{dt}_{\text{coll}} + \frac{d\rho}{dt}_{\text{rad}}$$

We shall now show with a simplified example how these transfers can produce a great increase of the anticrossing width. Consider two levels $a$ and $b$ of angular momentum $J = \frac{1}{2}$, where $|a\rangle$, $|a\rangle$ and $|b\rangle$, $|b\rangle$ are their Zeeman sublevels. The sublevels $|a\rangle$ and $|b\rangle$ are coupled by $V$ and anticross. The other two do not anticross but they are coupled to the anticrossing ones by collision. This is a limiting case of our $^4$He nD levels studies [3] in which the five Zeeman sublevels of the D levels are replaced by two.

We make the following assumptions on the collision process, whose validity in our experimental case will be discussed in a forthcoming detailed paper.

— The collisions do not couple $a$ and $b$. This corresponds to the Wigner spin rule in the case of singlet-triplet anticrossings. In this case $^{ab}\rho$, the projection of the density matrix $\rho$ into the subspace $a$, $bb\rho$, its projection into $b$, and $^{ab}\rho$, which represents the coherence between $a$ and $b$ are not coupled by collisions.

— The relaxation process is isotropic, i.e. the anisotropy due to the magnetic field has no influence on the collision process. This amounts to saying that the evolution of the atom under the influence of the Zeeman effect is negligible during the collision time.

One can show [6] that this isotropy hypothesis implies that the relaxation of each $^{xx}\rho$, with $x, x' = a, b$, depends only on two coefficients $^{xx}\gamma_{0}$ and $^{xx}\gamma_{1}$. More precisely, introducing the linear combinations of the density matrix components $^{xx}\rho_{\pm}$ which are proportional, within a subspace of spin $\frac{1}{2}$ to the mean values of magnetic moment operators (or Pauli matrices), one has

$$\frac{d}{dt} \langle M_x \rangle = \frac{d}{dt} \langle M_x \rangle_{\text{relax}} = \left( ^{xx}\rho_{+-} + ^{xx}\rho_{-+} \right)_{\text{relax}} = -^{xx}\gamma_{1} \frac{1}{2} \left( ^{xx}\rho_{+-} + ^{xx}\rho_{-+} \right)$$

$$\frac{d}{dt} \langle M_x \rangle = \frac{d}{dt} \langle M_x \rangle_{\text{relax}} = \left( ^{xx}\rho_{++} + ^{xx}\rho_{--} \right)_{\text{relax}} = -^{xx}\gamma_{0} \frac{1}{2} \left( ^{xx}\rho_{++} + ^{xx}\rho_{--} \right)$$

In comparison to the relaxation terms usually introduced in the Bloch equations, this shows two differences. First, the transverse and longitudinal relaxation times $T_1$ and $T_2$ are both equal to $1/^{xx}\gamma_{1}$, which is a consequence of the isotropy hypothesis.

Second, the modulus of $\mathbf{M}$ is not constant. $^{xx}\gamma_{0}$ takes into account the de-excitation processes, both radiative and collisional (quenching collision transfers to levels others than $a$ and $b$, which, in the case of the nD levels of He, are rather important due to the proximity of the nP and nF levels). We shall further simplify the problem by supposing $^{xx}\gamma_{0} = ^{bb}\gamma_{0} = \gamma_{0}$ and $^{xx}\gamma_{1} = ^{bb}\gamma_{1} = \gamma_{1}$, since a full calculation shows that this simplification changes nothing essential. The useful equations are then:

$$\frac{d}{dt} \left( ^{xx}\rho_{++} \right)_{\text{relax}} = -\frac{\gamma_{0}}{2} \left( ^{xx}\rho_{++} + ^{xx}\rho_{--} \right)$$

$$\frac{d}{dt} \left( ^{xx}\rho_{--} \right)_{\text{relax}} = -\frac{\gamma_{0}}{2} \left( ^{xx}\rho_{++} + ^{xx}\rho_{--} \right)$$

In summary, the explanation of the observed doubling of the anticrossing width is given by the collision-induced transitions between Zeeman sublevels.
2/(γ(0) + γ(1)) is then the average time during which the atom remains within one Zeeman sublevel, while 1/γ(0) is the average time during which it remains within a whole excited level a or b. Usually γ(1) ≫ γ(0) and the first time is considerably shorter than the second. Putting (4) into (1) a straightforward calculation leads to

\[ \frac{a_a \rho_{-\pm}}{\gamma} = \frac{n_a}{\gamma(0) - 2 |V|^2 \frac{1}{\gamma} + \left(\frac{h \cdot n_a}{\gamma}\right)^2} \]

and to similar expressions for \(bb \rho_{\pm\pm}\) and \(bb \rho_{\pm\mp}\), with:

\[ \frac{1}{\gamma} = \frac{1}{2} \left(\frac{1}{\gamma(0)} + \frac{1}{\gamma(1)}\right) . \]

One then finds that, if γ(1) ⪪ γ(0) (no pure quenching) the anticrossing signal appears also in \(\rho_{\pm\mp}\) and \(\rho_{\mp\pm}\). This is a consequence of the Zeeman transfer.

More important, the anticrossing shape remains Lorentzian as a function of \(E_a - E_b\), but its width is now

\[ \Delta E = 2 \sqrt{4 |V|^2 \frac{a_b \rho_{\pm\pm}(1)}{\gamma} + \left(h \cdot n_b \rho_{\pm\pm}(1)\right)^2} . \]

It is the \(a_b \rho_{\pm\pm}(1)/\gamma\) term which explains the anomalous increase of the width we have found experimentally. Indeed this term is the ratio between \(a_b \rho_{\pm\pm}(1)\), the relaxation time of the coherence between \(a + \) and \(b - \), and \(\gamma\), which is an effective relaxation time of the population of the levels. This ratio is equal to 1 at zero pressure for equal lifetimes of a and b, but is greater than 1 when there are collisions since a forward-backward transfer between, say, \(a - \) and \(a + \) brings back the population of \(a - \) but not the coherence between \(a - \) and \(b + \). More precisely, in our experimental case \(a_b \rho_{\pm\pm}(1) \sim \gamma(1)\), and we shall take

\[ a_b \rho_{\pm\pm}(1) = \gamma(1) = (1 + P) \Gamma \]

\[ \gamma(0) = (1 + KP) \Gamma , \]

where \(P\) is proportional to both the pressure and the depolarization cross-section, and \(K\) is the ratio between the quenching and the depolarization cross-section, usually much smaller than 1. All of these expressions are valid only one can neglect the back transfer from the quenching levels to a or b. Finally one obtains:

\[ \Delta E = 2 \sqrt{4 |V|^2 \frac{2 + (1 + K) P}{2(1 + KP)} + (1 + P)^2 (h \Gamma)^2} . \]

(6)

The factor which multiplies \(4 |V|^2\) varies from 1 at zero pressure to \((K + 1)/2 \) at high pressure. This last expression is usually \(\gg 1\), since \(K \ll 1\). Another consequence of the formula (5) is the prediction of a decrease, in the ratio of the polarization to the intensity signal which is independent of the excitation \(n_a\) and \(n_b\):

\[ \frac{\frac{a_a \rho_{\pm\pm} - n_a}{\gamma(0)} - \frac{a_a \rho_{-\pm} - n_a}{\gamma(0)}}{\frac{a_a \rho_{\pm\pm} + n_a}{\gamma(0)} + \frac{a_a \rho_{-\pm} + n_a}{\gamma(0)}} = -\frac{\gamma(0)}{\gamma(1)} = -\frac{1 + KP}{1 + P} . \]

This depolarization phenomenon has been experimentally verified.

3. Comparison with Bloch’s equations. — A better insight on these relaxation phenomena can be obtained by writing down the equations which relate population and coherence of the anticrossing \(|a - \) and \(|b + \)
levels in the case of steady state excitation. We introduce the linear combinations:
\[ u = a^b \rho_{-} + b^b \rho_{+}, \quad v = i(a^b \rho_{-} - b^b \rho_{+}), \]
\[ M_z = a^b \rho_{-} - b^b \rho_{+}, \quad \sqrt{M^2} = a^b \rho_{-} + b^b \rho_{+}. \]
(7)

These combinations are analogous to, but different from the expressions (4). In (4) all \( x \) and \( x' \) are consistently equal to \( a \) and/or \( b \), whereas in (7) there are mixed expressions corresponding to the populations of \( |a - \rangle \) and \( |b + \rangle \), and to the coherence between them. Eliminating in (1') (with \( \frac{dp}{dt} = 0 \)) the matrix elements of \( \rho \) corresponding to the non anticrossing states \( |a + \rangle \) and \( |b - \rangle \), one obtains (with \( V \) real):
\[ 0 = -i(E_a - E_{b+}) - a^b \rho_{-}^{(1)} u \]
\[ 0 = \nu(E_a - E_{b+}) - 2VM_z - ab^b \rho_{-}^{(1)} v \]
\[ 0 = 2VM - \gamma M_z + (n^*_a - n^*_b) \]
\[ 0 = (n^*_a + n^*_b) - \gamma \sqrt{M^2} \]
(8)

with \( n^*_a = n_a \gamma(1)^{0} \). The first three equations (8) are identical to the rotating frame steady state Bloch equations for the fictitious spin 1/2 associated to \( |a - \rangle \) and \( |b + \rangle \), with a detuning
\[ \delta \omega = g\mu_B B_0 - \omega = E_{a-} - E_{b+}, \]
a R.F. field \( B_1 = 2V/g\mu_B \) and a longitudinal time constant \( T_1 = 1/\gamma \) different from the transverse time constant \( T_2 = 1/a^b \gamma(1) \). This does not correspond to a real spatial anisotropy of the relaxation process, as is evident from eq. (4), but to the above-mentioned difference of relaxation times \( 1/a^b \gamma(1) \) for the coherence between \( |a - \rangle \) and \( |b + \rangle \) (which is the transverse quantity in (7) and (8)) and \( 1/\gamma \) for their population difference (which is the longitudinal quantity). The anomalous increase in width of the anticrossing signal is then equivalent to the saturation contribution to the linewidth \( 2 \sqrt{1/T_2^2 + \alpha^2} T_1/T_2 \) of the Bloch equations.

4. Conclusion. — We finally mention that we have extended this calculation to the pertinent case of the fine structure anticrossings of the \( n = 3D \) levels of \( ^6 \)He. This calculation is somewhat cumbersome and will be published later, together with more complete experimental results. An example of the fair agreement between theory and experiment is shown figure 2. The main point for this letter is that the simple calculation we have outlined here gives all the important results.

We thank the Service National des Champs Intenses de Grenoble (S.N.C.I.), which made possible the experiments reported here.

![Fig. 2. — Comparison between theory and experiment of the width of the anticrossing signal on the 4 1D and 4 3D levels of \(^4\)He. \( K = 1 \) corresponds to what would be expected in the absence of the factor \( a^b \gamma(1)/\gamma \) in the anticrossing linewidth.](image)
