Abstract. — Light scattering studies have demonstrated the existence of a large scale periodic organization of the amphiphilic aggregates in magnetically oriented lyotropic nematic samples. This was first interpreted structurally, in terms of fluctuations of the concentration of the aggregates. The study described here rather suggest a textural interpretation, in terms of a periodic angular distribution of the directors. This organization corresponds to the roll structure associated with the backflow induced by the orientation of the aggregates in the magnetic field. These experiments constitute the first observations of coherent patterns of hydrodynamic origin in lyotropic liquid crystals.

1. Introduction. — We have recently characterized a « nematic » lyotropic phase of type I (water-decanol-sodium decyl sulfate [1]) as an anisotropic aqueous solution of cylindrical aggregates of amphiphilic molecules [2]. These cylinders are packed with orientational order and the average direction of their axes defines the director. Light scattering studies of magnetically oriented samples have also demonstrated the existence of a large scale organization of the aggregates with a characteristic length of several µm [3]. This was interpreted as being due to intrinsic periodic fluctuations of the aggregate concentration [3] and the term « macromicelles » was proposed to characterize such a superstructure [4]. However, optical studies of the orientation process of a sample in a magnetic field show the transient appearance of a periodic orientational distribution of the directors in domains of several µm [2, 5] and, therefore, suggest an extrinsic textural interpretation of the light scattering patterns. We present here a study of the formation of the periodic domains and we show that their organization is due to the onset of a convective effect; we also show that the light scattering patterns are in fact related to the growth of the domains under the application of the field.

The conditions to investigate this phenomenon are those for the study of the Freedericksz transition in thermotropic nematic liquid crystals. The nematic phase is prepared in a planar configuration between glass plates, then a magnetic field is applied normal to the plates. The resulting competition between the magnetic susceptibility (which tends to align the director along the field) and the elastic energies (which tend to retain a uniform orientation of the directors consistent with the orientation at the surface of the samples) create a distortion of the field of directors at small magnetic fields. Beyond a certain threshold a convective instability develops which has been considered in detail for thermotropic liquid crystals [6].

Such experiments are in fact the first observation of a flow coupled with the orientation of the director in a lyotropic liquid crystals. In the following discussion it will be shown that the analogy with the similar situation in thermotropic liquid crystals is qualitatively though not quantitatively correct, as can be expected from the structural difference between both systems.

2. Experimental methods. — 2.1 Preparation of the sample. — The lyotropic phase is a mixture of 40.5% sodium decyl sulfate, 7.1% decanol and 52.4% water (% in weight). At room temperature it forms a nematic phase of cylindrical aggregates with positive anisotropy of diamagnetic susceptibility. This nematic phase is introduced by capillarity between glass plates separated by spacers from 20 to 1000 μm. The directors tend to align parallel to the glass plates and nearly planar domains, with a distribution of their orientations, are observed. A magnetic field is then applied parallel to the glass plates in order to obtain a planar single domain with uniform director ƞ₀ [7].

2.2 Experiments. — The domains are created by applying a magnetic field, ƞ₀ (several kG), perpendicular to the director ƞ₀ of the planar sample, i.e. perpendicular to the glass plates. The geometry of the experiments is defined in figure 1, the optical observations are made along either Oz or Oₓ. The observed growth and relaxation of the domains are quite slow (time scales of the order of several minutes). This permits to prepare the sample in a conventional electromagnet, then to observe the development of the patterns at various time intervals in a microscope outside the magnet. In order to check that this convenient method of observation does not overlook any fast process we also performed a similar experiment with samples containing 1% of ferrofluid (A01-200 G from ferrofluidics). In this case the required magnetic field could be created by Helmholtz coils mounted directly on the stage of the microscope [8]; this permitted a continuous observations of the evolutions of those samples. The observed phenomena appeared qualitatively similar for both types of samples, with and without ferrofluid, however a quantitative comparison is prevented by our limited understanding of the interaction between the ferrofluid and the structure.

3. Observations. — We shall present them in two steps according to the thickness of the sample :

3.1 Thick samples (10³ μm). — The application of the magnetic field along Oz induces the appearance in the (Oxy) plane of a coarsely periodic organization of isoclines with a wave vector along Oᵧ, as shown in figure 2. (After several hours in the field dark, quasi homeotropic, area develop and the texture evolves toward a more homogeneous one.) The stripes result from the focussing of the light rays by the distortion of the director. This is reminiscent of similar observations in thermotropic nematics [9] but there the organization is more coarse owing to the presence of defects which we did not succeed in eliminating. For this reason also a quantitative study of the organization from plots as functions of field strength and sample thickness is not yet possible. In the lack of samples with perfectly periodic organizations we shall limit ourselves to qualitative considerations. It appears that in a 15 kG magnetic field the distance between two stripes varies from 60 to 80 μm, it decreases when the field increases and does not appear commensurable with the thickness of the samples. The origin of such a periodicity in a nematic sample cannot be looked for in the competition between the magnetic and elastic terms only : it would lead to walls without organization [10]. The distortion of the director has to introduce a third term, for example a flexo-electric coupling, some layer arrangement as in smectic samples, or a hydrodynamic backflow [6], for a periodicity to appear. In order to discriminate between static and dynamic phenomena we completed observations of the samples in the plane (H₀, ƞ₀). Figure 3 shows the evolution of a line of defect initially parallel to ƞ₀. This line is straight before the application of the field (a), it becomes progressively distorted under the field, in an oscillating manner, with a wavelength of about 160 μm (b and c). Such a distortion of the line of defects shows that the field induces alternative displacements of matter within the sample every 80 μm. After several minutes in the field stripes, distant by about 80 μm and which run through the sample one glass plate to another, settle (d). These stripes in the plane (H₀, ƞ₀) are to be
Fig. 3. — Sideviews along Ox of a section of the sample parallel to the (H₀, n₀) plane taken at successive times: a) no field along Oz, a line of defects is visible parallel to n₀; b) immediately after the application of H₀ = 15 kG along Oz; c) after 5' in the field; d) after 15' in the field.

Combined with those in the plane normal to H₀ in a way which corresponds to the onset of the flow pattern between limiting glass plates represented in figure 4. We are therefore dealing with a hydrodynamic instability with wavelength of about 160 µm, not related to the thickness of the sample which is 10³ µm.

Fig. 4. — Combination of the stripes of figures 2 and 3d showing the flow pattern induced by the application of H₀ in a thick planar sample.

Finally, as shown in figure 5, the periodic light scattering pattern is associated with the growth of the domains when the magnetic field is applied; from the distance between the spots we recover the characteristic dimension of the domains. We are therefore dealing with a textural, not structural, phenomenon.

Fig. 5. — Diffraction diagrams obtained with a laser beam (λ = 6320 Å) parallel to Oz, the analyser is along Oy, the polarizer is along Ox. The sample is planar with n₀ along Oy (a), it has been submitted to the magnetic field H₀ along Oz (b).

Finally we observed qualitatively similar phenomena with much thinner sample (20 and 35 µm),...
the patterns are rather disordered but we can say that both wavelengths decrease with the thickness.

4. Discussion. — The patterns in figures 2 and 5 have been analysed as resulting from the composition of two flows of convective type induced by the application of the magnetic field. One is in the \((\mathbf{H}_0, \mathbf{n}_0)\) plane: the distance between the rolls (about 80 \(\mu\)m) does not depend upon the thickness of the sample when it is larger than about 100 \(\mu\)m. The other is in the plane normal to \(\mathbf{n}_0\): the distance between the rolls equals the thickness of the sample.

The primary effect to the field \(\mathbf{H}_0\) is to reorient the director \(\mathbf{n}_0\) of the planar sample in the \((\mathbf{n}_0, \mathbf{H}_0)\) plane. In principle in a nematic sample where the magnetic energy should be stored as elastic energy the uniform mode of the Freedericksz transition should be observed alone [10]. The appearance of a periodic mode along \(\mathbf{n}_0\) calls for the intervention of a term relaxing the elastic energy and the flow of matter, demonstrated in figure 3, suggests that it is a viscous relaxation. This aspect has already been considered in the case of thermotropic nematics [6]: the backflow associated with the rotation of the director makes an unstable periodic mode grow faster than the stable uniform mode, the period increases with the thickness in a bounded medium and stabilizes to a finite value in an unbounded medium, it decreases when the field increases. This description qualitatively agrees with our observations on the first family of rolls, our thinnest samples (20 and 35 \(\mu\)m) would correspond to the bounded situation whereas the thickness ones (180, 320 and 1 000 \(\mu\)m) would correspond to the unbounded situation, as well as the larger samples used for the first light scattering study [3]. The occurrence of a second family of rolls is not foreseen in this model; similar experimental situations also exist in thermotropic samples but this second mode, which has a larger wavelength than the first, is a weak correction which has not been considered theoretically.

5. Conclusion. — According to our study the existence of superstructures in the organization of the aggregates, i.e. periodic fluctuations of their concentration, cannot be inferred from light scattering experiments at the moment. Those lyotropic liquid crystal can still be depicted as assemblies of anisotropic aggregates with some orientational order of the nematic type. A central question for the understanding of lyotropic nematics is: how do they differ from ordinary nematics? In other words: the basic structural element is no longer one molecule but an aggregate of molecules, does this have any qualitative, or at least quantitative, consequence for the properties of the phase? So far static studies of birefringence, texture and alignment in a magnetic field suggest the properties of the director to be qualitatively similar in both cases [11, 7]. The observation of hydrodynamic instabilities described here does not invalidate this point of view. Therefore we are left at the moment with the eventuality of quantitative differences for the constants characterizing the materials. We may attempt some comparisons. A first information readily obtainable is the relaxation time, \(\tau = \gamma_1/\Delta \chi H^2\), of the orientation in a magnetic field; it is about 0.1 s in thermotropics and one minute or more in lyotropics. As the anisotropy of susceptibility, \(\Delta \chi\), may be smaller in lyotropics by a factor 10, [12], the rotational viscosity, \(\gamma_1\), may be larger. This is conceivable owing to the large dimensions of the cylindrical aggregate [7].

A second information concerns the elastic constant and may be deduced from the wavelength, \(\lambda\), of the first family of rolls studied above. Following [6] in the unbounded situation \(\lambda^2 \approx D_\perp \tau\), where the diffusivity \(D_\perp\) is the geometrical mean between the diffusivity of orientation \(K/a\) and the viscous one \(\eta_2/\rho\). For thermotropic [9] and lyotropic samples in a 15 kG field \(\lambda/2\) are respectively 16 and 80 \(\mu\)m so that \(D_\perp\) is larger in the first case than in the second one by more than one order of magnitude. If we consider that \(\eta_2\) and \(\gamma_1\) are of the same order of magnitude and that \(\rho \sim 1\) in both cases it ensues that the elastic constant, \(K\), is smaller in the lyotropic phase by about two orders of magnitude. This is supported by a rough estimation of \(K\) considering that it is the ratio of the interaction energy between nematic objects and their typical dimension [13]: here the energy which maintains the orientational order is about 300 K, or

\[
0.4 \times 10^{-13} \text{ erg} \quad [14],
\]

the dimension 40 \(\AA\), so that \(K\) would be about \(10^{-7}\) dynes whereas it is \(10^{-9}\) dynes in a thermotropic nematic; moreover the flexibility of amphiphilic aggregates might also contribute in decreasing \(K\).

Indeed the interest of lyotropic materials, when compared to thermotropic ones, would be their extreme variability: the shape, size and packing of the aggregates are very sensitive to the nature, concentration and temperature of the constituents in a way which might affect greatly the constants of the material.
