Abstract. A method is presented, which combines optical excitation and electrical refilling of deep levels, allowing one to measure the majority carrier capture cross-section for minority carrier traps: e.g., $\sigma_n$ for a hole trap in n-type material. This method has been used to characterize many deep levels in gallium arsenide. The following results are obtained: the main electron trap « EL 2 » is not a hole lifetime killer; the temperature coefficient of the ionization energy for several levels, including the Cr level used for compensation in semi-insulating crystals; very large ($10^{-15}$ cm$^2$ or more), and very small ($10^{-21}$ cm$^2$) electron capture cross-sections for two of the levels; possible capture mechanisms for these last cases are mentioned.

Introduction. The increasing interest for the compound semiconductors, together with the refinement of the characterization methods, such as Deep Level Transient Spectroscopy [1] (D.L.T.S.), has led to a better knowledge of the many different deep levels which one can find in the forbidden band gap of the semiconductors. In the particular case of gallium arsenide numerous traps have been classified by several authors [2-6]; nevertheless, their origin is known only for a few of them which have been voluntarily introduced in the material during the growth [2] and then characterized. The influence of these traps on the optical and electrical properties of the semiconductor depends mainly on three characteristic properties of the level: its activation energy, concentration and capture cross-section for the free carriers. Some traps, such as the level due to the presence of chromium in the material, are very deep; they are then used for compensating the semiconductor in order to get the semi-insulating substrates needed for the realization of some devices. A detailed knowledge of their properties is then of first importance. Another important stimulus for the study of deep levels is the search for recombination centres responsible for the discrepancy [7] between the measured diffusion lengths and those expected in pure GaAs, and actually observed in the best L.P.E. crystals [8].

In this paper, many measured carrier capture cross-sections are given for levels occurring in GaAs. The following informations may be deduced from these measurements: about the activation energy of the traps, the variation of the activation energy with temperature, the possible influence of the levels on the electrical and optical properties of the material and of the device, and finally about the capture mechanisms. We shall show in addition that the measurement of the capture cross-section is a way to separate levels for which the thermal emission rates are very similar at a given temperature.

In the following, we deal with many different levels appearing in gallium arsenide, and therefore in order to avoid confusions, we shall use the nomenclature given in references [3, 4 and 5] and just recall in brackets the label given by different authors.

1. Background. In an effort to identify the capture mechanisms, C. H. Henry and D. V. Lang have studied in GaAs and GaP the variation of electron and hole capture cross-sections of some traps with...
temperature [2, 9]. The studied levels are either unidentified traps arising in the as-grown material (HL 5 and HL 2 in L.P.E. layers and EL 2 in V.P.E. ones), or traps due to the presence of a given impurity in the material (mainly transition elements have been characterized : Cu, Fe, Cr). They have found that both the order of magnitude and the variation of the electron capture cross-sections with temperature agree with a theory where multiphonon emission mechanism (M.P.E.) plays a leading role. Nevertheless, in the particular case of gallium arsenide none of the characterized traps appears to be able to really act as a recombination centre, that is to say, a centre having large capture cross-sections (10\(^{-16}\) cm\(^2\) or larger) for both free electrons and free holes. Indeed, the transition elements Cr, Fe, Cu, have large \(\sigma_p\) values, but the \(\sigma_n\)'s are small, in the (10\(^{-19}\), 10\(^{-20}\)) cm\(^2\) range.

Nickel has been reported [7] to reduce the carrier lifetime, but as yet, a detailed electrical characterization of Ni-related deep levels has not been carried out.

Among the defects related to a given growth process, both \(\sigma_n\) and \(\sigma_p\) are known only for the traps HL 5 and HL 2 (respectively A and B in reference [2]) which are typical of L.P.E. material. Roughly speaking, the electron and hole capture cross-section for HL 2 are similar to those of the above mentioned transition elements, but the level HL 5 has an electron capture cross-section which is nearly 3 orders of magnitude larger at room temperature, so that, due to its hole capture cross-section [2] which is also very large (10\(^{-15}\) to 10\(^{-14}\) cm\(^2\)), it could act in some cases as a recombination centre.

Nevertheless, the generally held view is that the best carrier lifetimes and diffusion lengths are obtained in L.P.E., and the worst one in melt grown material [10]. More effective recombination centres are then expected in this last material.

As a matter of fact, it is now well known that the upper half of the forbidden band-gap of GaAs can accommodate many different discrete levels which probably arise from various complex defects [11]. These levels are electron traps, characterized by relatively large values of their electron capture cross-section \(\sigma_n\), and it would not be surprising if they had large \(\sigma_p\)'s too since they are very deep. They exist mostly in melt grown material, have smaller concentrations in vapour phase epitaxy (V.P.E.) ones, and are entirely absent in liquid phase epitaxy (L.P.E.) layers. This may be correlated to the above mentioned variation of the diffusion lengths in these materials, and in fact, a tentative correlation was made recently [12] between the excess hole lifetime and the presence of a level which might be called the main electron trap of GaAs crystals, that is EL 2 ; this level also called O in many papers [2, 13], has been related to oxygen impurity in the past [14].

In part 2, we describe the technique, based on ODLTS [15], which has been used in order to determine the majority carrier capture cross-section for minority carrier traps (for instance \(\sigma_p\) for a hole trap in n-type material), and which can be applied to p-n junctions as well as to Schottky barriers. The way used to analyse the data is briefly described in the same paragraph. The results are given in part 3. In part 3.1., we present the results obtained in as-grown material : \(\sigma_p\) for the electron trap EL 2 has been determined at 320 K, and this is the first report of an experimental \(\sigma_p\) value for an electron trap in as-grown GaAs. The \(\sigma_n\) of this trap has been reported previously [2, 16] ; however, since more recent investigations [17] have shown that the data should have been analyzed more rigorously, we have found different and more accurate \(\sigma_n\) figures up to very low temperatures. Both \(\sigma_n\) and \(\sigma_p\) have also been determined as a function of temperature for the chromium level. These results have already been published previously in the literature [2], but our data \(\sigma_p\) for chromium are quite different. From the comparison of capture with emission results, we deduce a rough estimation of its temperature coefficient. Finally, three results of electron capture cross-sections are given : two of them are the largest electron capture cross-sections which have ever been found in GaAs crystals, the third one shows that the corresponding level can act as an effective recombination centre. Part 3.2. is devoted to the study of traps arising in V.P.E. electron irradiated layers : the \(\sigma_p\) of one electron trap and four hole traps have been measured for the first time, three of them having never been reported as yet [18]. Part 4 is the conclusion.

2. Experimental. — 2.1 Principle of operation. — Our method combines the optical excitation and the electrical refilling of the traps : a short light pulse of high intensity is first sent on the sample, inducing the excitation of the traps. A OV bias pulse is then applied to the diode, inducing the refilling of the traps.

Fig. 1. — Timing of the sequence showing the capacitance variations during and after the light and bias pulses : the dashed lines indicate the capacitance variations without any bias pulse.
with majority carriers. Figure 1 shows the timing of the sequence together with the capacitance variations of the sample; figure 2 is an example of resulting D.L.T.S. spectra obtained in varying the duration of the OV bias pulse.

![Fig. 2. ODLTS spectra recorded on a Cr-doped n-type L.P.E. GaAs sample, for various values of the refilling OV bias pulse. Emission rate window : 0.88 s⁻¹ ; reverse bias : 10 V.](image)

This method has the advantages of optical D.L.T.S. in that it allows an assessment of the minority carrier traps in Schottky barriers as well as in p-n junctions; in addition, the optical excitation of the traps with sub-band-gap light ensures an uniform refilling of the traps in the whole depleted layer, which is seldom the case, when electrical injection is used with asymmetrical p⁺-n junctions. Finally, it allows a precise determination of the cross-sections for the carriers, even in the complex case where the peaks due to several traps are partly mixed; figure 3 is such an example in p-type material, where the negative peak due to EL 2 is partly superimposed to the positive peak due to the chromium level HL 1: curve (a) is obtained with the light pulses applied alone, curve (b) with a 200 ns bias pulse applied alone, and curve (c) is obtained when the same bias pulse is applied after the light pulse. The negative peak of spectrum (a) is mainly due to EL 2, the (positive) peak of spectrum (b) is due to HL 1. Spectrum (c) includes contributions from both HL 1 and EL 2; however, this difficulty is overcome by subtracting curve (b) from curve (c). In this way we get the differential spectrum (d) in which the HL 1 contribution has been eliminated. From the dependence of the peak height (curve (d)) versus bias pulse duration, the σᵥ of EL 2 can be determined. For the majority carrier traps cross-section measurements, the same technique as to the one described by D. V. Lang in reference [1] has been used.

2.2 EXPERIMENTAL SET-UP. — Our set-up, based on the use of a programmable calculator has already been described [19]. For the capacitance measurements, we use a Boonton 72 B capacitance meter; however, in order to be able to apply very short and clean bias pulses, we devised a special arrangement using reed relays which connect the sample alternatively to the capacitance meter and to a pulse generator. The pulse generator has a d.c. offset which is exactly equal to the reverse bias applied through the capacitance meter. Switching the sample from the capacitance meter to the pulse generator, and vice-versa, is controlled by the calculator and follows the close-before-open principle, so that the sample sees the same reverse bias all the time, except during the bias pulses when it goes to zero. The timing of the whole sequence is repetitively generated by the calculator.

2.3 RESULTS ANALYSIS. — The use of a YAG laser of about 200 mW at 1.06 μ to get the light pulse allows us to reach the saturation in a few ms; a given level is then filled according to the ratio : eₙ₀(eₚ₀ + eₚ₀), where eₙ₀(eₚ₀) is the optical emission rate toward the conduction (valence) band.

During the OV bias pulse, the traps refill with majority carriers with a time constant

\[ \tau = (nσᵥ<v>)^{-1} \]

in n-type material (\(\tau = (ρσᵥ<v>)^{-1}\) in p-type material), where \(n(p)\) is the doping level, \(σᵥ\) the electron (hole)capture cross-section of the traps for the carriers, \(<v>\) the mean square thermal velocity of the carriers. From the slope of the variation of the D.L.T.S. peak height with the bias pulse duration, we deduce \(σᵥ\).

It has been shown recently [17], that special care must be devoted to the analysis of the carrier capture
We have therefore used a reverse bias as large as possible (10 V in most cases) in order to minimize these effects, and the value of $\sigma$ was deduced using only the first points which are aligned (Fig. 5). (They generally represent at least 50% of the whole amplitude of the signal.) It is worth noting that, in the case of a minority carrier trap (e.g. a hole trap in n-type material), at the edge of the depleted layer, the electrons (or holes) recombine with the trapped holes (electrons). The thickness of the layer involved: $\lambda_{\text{min}}$, depends on both $n$ and $\sigma_n$ (or $p$ and $\sigma_p$) and may then be small in some cases since we are concerned with a minority carrier trap. A good fit with the exponential law can therefore be obtained in that case, since the contribution of the traps inside $x_0$ to the capacitance variation, varying as $x_0 - x$, is small.

Figure 6 is such an example, obtained for the hole trap due to the chromium level in n-type material showing the nearly ideal exponential variation of the refilling rate as a function of the OV bias pulse duration.

These features: uniform refilling inside the depleted layer, reverse bias as large as possible, measurement of the refilling time constant using only the first points aligned, are of first importance for the accuracy of the results. Given our experimental conditions, an uncertainty by about a factor of 2 can be accounted in most cases for the values of $\sigma$ given in the present work.

The range of capture cross-sections that we can measure depends on the doping level of the material and on the value of the shortest pulse which can be applied to the sample (about 30 ns in our case). For example, with a carrier concentration of $1 \times 10^{15} \text{ cm}^{-3}$, we are able to measure capture cross-sections as large as about $5 \times 10^{-16} \text{ cm}^{2}$.
The minority carrier traps that can be assessed using the optical method are only those which give rise to a peak in the O.D.L.T.S. spectrum: the ratio \( e_n^0/(e_n^0 + e_p^0) \) must not be too small, as it is the case for example for the iron level [3].

It has been shown [20] that, assuming a linear dependence of the ionization energy \( E_i \) of a bound state with the temperature: \( E_i = E_i - \alpha T \), the temperature coefficient \( \alpha \) may be deduced from the knowledge of emission rate data: \( e_n \) together with the variation of the capture cross-section \( \sigma \) with the temperature. If we assume for the latter an exponential dependence with \( 1/T \):

\[
\sigma = \sigma_\infty \exp \left(-\frac{E_B}{kT}\right),
\]

\( e_n \) can be written:

\[
e_n = \gamma T^{\prime} \sigma_\infty \exp \left(\frac{\alpha^*}{k}\right) \exp \left(-\frac{E_B}{kT}\right)
\]

where \( k \) is the Boltzmann constant and \( \gamma \) a numerical constant depending on the effective density of states in the conduction or valence band, and on the effective mass of the carriers.

Emission rate measurements yield \( (E_i + E_B) \) together with \( \sigma_\infty \). Capture cross-section measurements yield \( E_B \) and \( \sigma_\infty \). The temperature coefficient \( \alpha \) may then be deduced from these complementary measurements, and it will be given below for some of the studied traps. We recall that \( \alpha^* = \alpha + k \ln g \) for electron traps, and that \( \alpha^*_p = \alpha - k \ln g \) for hole traps, \( g \) being the degeneracy factor of the trap.

3. Results. — 3.1 AS-GROWN MATERIAL. — 3.1.1 EL 2. — In order to obtain an estimation of the influence of the trap EL 2 on the properties of the crystal, we have used the above method to determine its hole capture cross-section: p-type bulk material \( (p = 1 \times 10^{17} \text{ cm}^{-3}) \) has been assessed; an \( n^+ \) epitaxial layer of about 2 \( \mu \) was deposited to get a diode. At the temperature \( T = 320 \text{ K} \), the hole capture time constant we found is about 180 ns, which leads to the value \( \alpha^* = 2 \times 10^{-18} \text{ cm}^2 \). The minority carrier lifetime \( \tau_m \) in the case where it is governed by a recombination centre, is given by the relationship: \( 1/\tau_m = C_p n_T \). If we introduce the measured value of \( C_p = \sigma_\infty \langle \nu \rangle \), as the minority carrier lifetime is \( 2 \times 10^{-8} \text{ s} \) or less, in pure n-type GaAs [10], the recombination due to EL 2 would become important if its concentration was larger than \( 10^{18} \text{ cm}^{-3} \). Such a high concentration of traps has never been observed in as-grown GaAs crystals, and we can then conclude that the suggested correlation between the concentration of the trap EL 2, and the minority carrier diffusion length in reference [12] is accidental and that the level EL 2 doesn’t affect the hole diffusion length in n-type gallium arsenide.

The electron capture cross-section of the trap EL 2 has been determined as a function of temperature from 273 K to 52 K. As pointed out before, special care has been taken to avoid erroneous measurements: we used a Schottky barrier (gold evaporated) made on a low doped sample \( (n = 1.3 \times 10^{15} \text{ cm}^{-3}) \) and the applied bias was 10 V. Only the trap EL 2 was present in this sample. The values of \( \alpha^* \) deduced of our measurements are therefore expected to be more reliable than previously published one [2, 17], and they extend the temperature range until 50 K. They are intermediate between the values of reference [2 and 17], but we find also that they are thermally activated until about 80 K with an activation energy \( E_B = 0.066 \text{ eV} \) and a preexponential factor \( \sigma_\infty = 6 \times 10^{-15} \text{ cm}^2 \). This result is displayed graphically on figure 7. Our values for \( \sigma_\infty \) and \( E_B \) are slightly different of those given in the literature [2]. Emission rate measurements yield for \( \sigma_\infty \exp \alpha^*/k = 8.8 \times 10^{-14} \text{ cm}^2 \), and we can therefore deduce: \( \alpha = 2.9 \times 10^{-4} \text{ eV K}^{-1} \) (taking \( g = 1/2 \) as suggested in [20]).

![Graph showing electron capture cross-section as a function of temperature for the studied traps.](image)

3.1.2 Chromium. — The electron and hole capture cross-sections have also been determined for the chromium related level HL 1 as a function of temperature and are quite different of those reported in the literature [2]. An important point is that we have not been able, using DLTS or ODLTS, to detect any electron trap, having a concentration of the same order of magnitude than HL 1, in the chromium doped layers, whether they are n- or p-type, and whether they are bulk, V.P.E. or L.P.E. ones: we always find for chromium a single hole trap at about 0.9 eV. Its electron capture cross-section is thermally activated with a slope \( E_g = 0.117 \text{ eV} \) and a preexpo-
nential factor $\sigma_\infty = 1.3 \times 10^{-17}$ cm$^2$ (Fig. 7). For the hole capture cross-section, we find that $\sigma_p$ is slightly increasing above room temperature, leading to $\sigma_p = 1 \times 10^{-16}$ cm$^2$ (see Fig. 8). The temperature coefficient of the chromium level can thus be estimated to be about: $\alpha = 5.2 \times 10^{-4}$ eV K$^{-1}$, which is nearly the temperature coefficient of the GaAs band-gap. The important conclusion is then that the chromium related trap is pinned to the conduction band.

It appears then that this trap could be in some cases an effective recombination centre, in view of the large values of its $\sigma_\infty$ and $\sigma_p$.

The electron capture cross-section of EL 5 and EL 11 have been assessed in a low doped material ($n = 1.2 \times 10^{14}$ cm$^{-3}$) using a Schottky barrier (gold evaporated), but we have been able to really determine $\sigma_n$ only for EL 11: $\sigma_n = 2 \times 10^{-15}$ cm$^2$ at $T = 100$ K, since essentially no change in the peak height of EL 5 occurred with pulses as short as 50 ns. We can therefore estimate its $\sigma_n$ to be larger than $5 \times 10^{-15}$ cm$^2$ at $T = 200$ K, which is the largest value ever observed for an electron trap in GaAs crystals. The result for EL 11 is striking because the $\sigma_n$ we measured is larger than the value deduced from emission rate measurements:

$$\sigma_n \exp \frac{\alpha'}{k} = 3 \times 10^{-16} \text{ cm}^2$$

and it follows that either $\sigma_n$ decreases with increasing temperature, or that the temperature coefficient of this trap is negative: in that case, assuming that $\sigma_n$ is constant with temperature, we find

$$E_T = (0.17 + 1.6 \times 10^{-4} \text{ T}) \text{ eV}.$$

At the opposite, the value of $\sigma_n \exp \alpha'/k$ calculated for EL 5 is about $10^{-13}$ cm$^2$ : the level probably has a zero temperature coefficient and it follows the conduction band. This trap is definitively not the same as the level E 3 as previously suggested [4]; the latter, created by electron irradiation is attributed by D. V. Lang to a Ga vacancy [21] and has a much smaller electron capture cross-section ($1 \times 10^{-16}$ cm$^2$) at the same temperature.

3.2 ELECTRON IRRADIATED MATERIAL. — Electron irradiation at room temperature gives rise in L.P.E. GaAs to a number of traps, which have been studied and classified by D. V. Lang [21]. Mainly five electron traps, labelled E 1 to E 5, and one hole trap H 1 have been reported as yet. Electron irradiation defects are also studied in our laboratory [22], in V.P.E. or bulk material: in addition to the levels studied by D.V. Lang, we find some new ones which are likely to be related to the presence of impurities in the layers. They are labelled HL 13 ($E_h + 0.96$ eV), HL 14 ($E_h + 0.25$ eV), which is the same as H 1, HL 15 ($E_h + 0.56$ eV) and HL 16 ($E_h + 0.79$ eV). Figure 9 is a typical example of a D.L.T.S. spectrum recorded on a p-type V.P.E. layer annealed at 200 °C for 6 min., after having been irradiated with 1 MeV electrons at a dose of $3 \times 10^{16}$ cm$^{-2}$. We clearly observe the new hole traps HL 13, HL 15, HL 16, and it must be noticed that HL 16 appears at the same temperature as the level HL 2 [3] characteristic of L.P.E. as-grown layers, and that HL 15 appears at the same temperature as HL 3 often detected in V.P.E. layers.
The electron capture cross-section of HL 16 has been measured in a n-type layer \( (n = 2.1 \times 10^{16} \text{ cm}^{-3}) \), irradiated in a modified Van De Graaf accelerator with 1 MeV electrons at a dose \( 7 \times 10^{15} \text{ cm}^{-2} \). The sample has been then annealed at 300 °C for 15 min. in order to get rid of some of the other levels which were also created by the electron irradiation. The electron refilling time constant has been found to be almost constant from 290 K to 335 K, leading to \( \sigma_n = 3 \times 10^{-21} \text{ cm}^2 \) : this suggests that M.P.E. [9] doesn’t play an important role in the capture process, as it is the case for the level HL 2 (see Fig. 7), and the cross-section is appreciably lower at the same temperature : HL 16 is then different from the level HL 2 (labelled « B » in (1)) at \( E_v + 0.71 \text{ eV} \) which is found in as-grown L.P.E. layers. This is corroborated by the measurement of \( \sigma_n \) for this trap as shown below.

The hole capture cross-sections have been measured in p-type, Zn doped, V.P.E. layers with a doping level around \( 1.7 \times 10^{16} \text{ cm}^{-3} \); for the traps E 5, HL 14 and HL 16, the electron irradiation dose at 1 MeV was \( 8 \times 10^{15} \text{ cm}^{-2} \), and the respective \( \sigma_p \)'s are given in table I. The hole capture cross-section for HL 16 is 2 orders of magnitude lower than for the level HL 2, and they cannot be confused any more. The E 5's \( \sigma_p \) is quite large for an electron trap, but certainly not enough for making it a lifetime killer, whereas the hole capture cross-section of HL 14, equal to \( 1 \times 10^{-18} \text{ cm}^2 \), could make this trap a lifetime killer in n-type material if introduced in sufficiently large concentration.

The trap HL 15 has its D.L.T.S. emission peak at nearly the same temperature as HL 3, but its \( \sigma_n \) is two orders of magnitude lower. Figure 10 gives the spectra obtained with two different durations of the refilling bias pulse : the shoulder observed on the low temperature side of the peak is due to an additional unidentified trap.

Finally, special mention must be devoted to the trap HL 13 which is the deepest trap ever found in gallium arsenide : D.L.T.S. measurements yield for HL 13 : \( E_v = 0.96 \text{ eV}, \sigma_p \exp \alpha/\kappa = 6.7 \times 10^{-15} \text{ cm}^2 \), and we have measured at

\[ T = 420 \text{ K}, \quad \sigma_p = 1.5 \times 10^{-18} \text{ cm}^2. \]

In spite of this low value for \( \sigma_p \) and of the depth of the trap in the band-gap, it acts as a hole trap : its \( \sigma_n \)

must then be extremely low, and in fact, if we do the same calculation as for HL 10, we find

\[ \sigma_n \leq 5 \times 10^{-19} \text{ cm}^2 ; \]

as for HL 16, it would be interesting in that case to search for Auger effect.

4. Conclusion. — The measured capture cross-sections are summarized in table 1, and displayed graphically on figures 7 and 8. The presented method for the measurement of \( \sigma_n \) in n-type material (or of \( \sigma_p \) in p-type material) for the minority carrier traps, combining optical and electrical refilling of the traps, has allowed us to determine the minority carrier cross-section of six levels appearing either in as-grown or in 1 MeV electron irradiated V.P.E. GaAs. Among all the levels which have been characterized in gallium arsenide, only some of them are expected to have an undesirable influence on device operation, and we have tried to identify them: the most common trap of GaAs: El 2 appears to be harmless, but the hole trap HL 10, due to its large electron and hole capture cross-sections, could be in most cases an effective recombination centre. In addition, special attention must be devoted to the traps EL 5 and EL 11, for which the electron capture cross-sections are already very large at low temperature.

Electron and hole capture cross-section measurements have appeared to be a good way to separate levels which have almost the same activation energy: the level HL 15 created in V.P.E. GaAs by 1 MeV electron irradiation is different from the iron level HL 3 which has nearly the same thermal emission rate, but a larger \( \sigma_p \); in the same way, the hole trap HL 16 created in 1 MeV V.P.E. or L.P.E. irradiated GaAs, is different from the level HL 2 at \( E_C + 0.71 \text{ eV} \) which is typical of L.P.E. layers.

Our results about the hole capture cross-section of the chromium level show clearly that it does not vary with temperature and also that this level is pinned to the conduction band whereas it is a hole trap; this determination of its position in the band gap as a function of temperature is of first importance for the understanding of the properties of the semi-insulating substrates.

Finally, about the capture process, for at least three of the studied electron capture cross-sections, the value of \( \sigma_n \) or its variation with temperature are not typical of M.P.E. mechanism [9]: the trap HL 16, created by electron irradiation, has a very small \( \sigma_n \), not thermally activated, and it would be interesting to measure it with various doping levels in order to search for Auger effect. For the traps EL 5 and EL 11, already at low temperature, \( \sigma_n \) is in the calculated and extrapolated range of \( \sigma_{n0} \): there is no thermal activation, and therefore, either there is no lattice relaxation, or it is very large so that in the c.c. diagram [9] the crossing point of \( E_T \) with \( E_C \) is at \( Q = 0 \). It is worth noticing that EL 11 looks in that case quite similar to the « DX » centre [23] existing in GaAlAs layers, but in a very much smaller concentration. This crucial point could be assessed in studying its optical properties.

Acknowledgments. — We are indebted to the L.E.P. epitaxy group for V.P.E. (AsCl\(_3\)/Ga process) p-type layers, to J. Bourgoin for electron irradiation, and to Dr Woodard of Cornell University (U.S.A.) for providing n and p-type L.P.E. layers.
