Abstract - The influence of small amounts of AlCl₃, ZrCl₄ and BCl₃ on CVD of TiC with a TiCl₄/H₂/CH₄ gas mixture under reduced pressure was investigated. Grain refinement of TiC coatings could be obtained by adding dopant compounds at suitable concentrations. Their interactions are explained by the formation of co-deposited phases which interfere with the growth of TiC crystals and promote surface nucleation. The effectiveness of dopants to decrease the grain size is explained by the formation of thin films on the growing TiC crystals having a different chemical bonding than TiC.

1. INTRODUCTION

Cutting tools coated with TiC by chemical vapor deposition (CVD) are widely used today because of their high wear resistance and toughness. Many investigations have been carried out to further enhance the cutting performance of coated tools. One approach is to develop new coating materials such as mixed layers (e.g. Ti-Zr-C[1], Al-O-N [2]) or mixed crystals (e.g. Ti-Al-N [3], TiB-C [4]). Another approach is to improve the properties of the coating materials by forming a finer grained structure or a more uniform layer thickness, which can be achieved by the improvement of the technological process, for example by controlling impurities [5-6].

The ternary systems of Ti-Al-C, Ti-Zr-C and Ti-B-C have already been investigated using the CVD method [1,7] and the PVD method [3,8-9]. It was also reported [7,10] that Al or Mg as dopants in the deposition process of TiC had a positive catalytic influence on the deposition rate and the grain refinement. However, there is still no theoretical explanation for the mechanism of this influence. In the work reported here the influence of small amounts of AlCl₃, ZrCl₄ and BCl₃ additions on the deposition process and on the morphologies of TiC coatings was investigated.

2. EXPERIMENTAL PROCEDURE

The experimental setup for TiC deposition is described in Fig.1. The TiC CVD process was carried out with the system TiCl₄/H₂/CH₄ under the conditions indicated in Table 1. ISO K20 cemented carbide (commonly called WC-Co) was used for the substrates. Before deposition all substrates were cleaned with methanol. The solid impurities AlCl₃ and
ZrCl₄ were sublimated. The doping concentration was controlled by the temperature in a sublimator and the flow rate of the H₂ carrier gas. A known quantity of BCl₃ was feed into an Ar-filled bottle with constant volume. During the BCl₃ addition to the CVD reactor the amount of B added was controlled by the pressure drop occurring in the bottle.

3. RESULTS

3.1. Growth rate

The TiC growth rate did not change when ZrCl₄ was added as a dopant, but increased with the addition of AlCl₃ and of BCl₃. With AlCl₃, the growth rate increased at low and decreased at high doping concentrations. However, for BCl₃, it increased with doping concentration higher than 100,000 ppm (Fig.2).

3.2. X-ray diffraction analysis

Table 2 lists the solid phases deposited after the CVD reaction with different impurities and concentrations. For AlCl₃ and ZrCl₄, no phases other than TiC and eta-phase (W₆Co₆C) could be detected, while for BCl₃, the TiB₂ and CoWB peaks were observed at dopant amounts of 100,000 ppm and higher.

3.3. Grain size

The changes of the TiC crystal habit at different doping concentrations and impurities are shown in Fig. 3. Grain refinement of the TiC coating could be obtained by doping with AlCl₃ or BC₁₃. For both impurities there were so-called "critical concentrations" at which the grain refinement effect showed a maximum [11]. Below the critical concentrations the grain size decreased with increasing dopant concentration and above it increased with increasing dopant concentration. The critical concentrations were different for each impurity. The TiC crystal morphology changed remarkably when BC₁₃ exceeded the critical concentration. This change could be due to the increasing amounts of TiB₂ deposition.

4. DISCUSSION

The grain refinement of the TiC coating by AlCl₃ or BC₁₃ can be explained by the formation of new phases which were co-deposited simultaneously with the TiC by the reaction between the doped impurity and the reaction gas. Similar to an intermediate layer in a multilayer coating, a co-deposited phase inhibits the continued growth of the crystals and forces a new nucleation step on the surface, which basically promotes the grain refinement of the main constituent.

In the case of BC₁₃ doping, X-ray diffraction and electron probe micro analysis showed TiB₂ formation and co-deposition when high BC₁₃ amounts (above 100,000 ppm) were added. The co-deposition of the two phases leads in this case to the grain refinement. However with AlCl₃ and ZrCl₄ no co-deposited phases could be detected, either by X-ray diffraction or by electron probe micro analysis, at any of the
concentrations. This might be due to the very small amounts of the co-deposited phase, i.e. amounts below the limit of detection (0.1 at%) for electron probe micro analysis. The reason that such small amounts of the co-deposited phase influence the grain size could be a difference in chemical bonding. These films are very thin and could even be monomolecular. For AlCl₃ addition the carbide Al₃C₄, which has an ionic bonding, might be the co-deposited phase. Such a mechanism could be explained as follows:

Stage 1: TiC crystals grow on the substrate surface.
Stage 2: A very small amount of Al₃C₄ (e.g. an extremely thin film) might deposit on the TiC crystal facets. Such a simultaneous deposition of a phase with ionic bonding should stop the further growth of TiC crystals.
Stage 3: New heterogeneous nucleation of TiC must occur on this extremely thin film.

The consequence is a reduction of the grain size. This mechanism is shown schematically in Fig.4. Just a small amount of AlₓCᵧ on the crystal surface should restrain the TiC crystal growth more effectively than ZrC or TiB₂ because of the greater difference in chemical bonding as well as the structural difference between the TiC (metallic bonding, cubic structure) and AlₓCᵧ (ionic bonding) than between the TiC and ZrC or TiB₂ (metallic bonding). Table 3 shows the chemical bonding and structures of selected hard materials. For the ZrCl₄ additions, no effect on the grain refinement was observed. It can be assumed that a new nucleation of TiC is not necessary during the co-deposition of the two phases because their chemical bondings and structures are similar to those of TiC.

Stage 1: TiC crystal growth

Stage 2: Formation of an extremely thin film of AlₓCᵧ and stopping of the TiC crystal growth.

Stage 3: Nucleation of TiC on the extremely thin film

Similar results were reported by P. Wilhartitz et al. [12]. They analyzed Al₂O₃-CVD with CS₂ additions using SIMS and reported that carbon incorporated in the Al₂O₃ coating appeared to be responsible for the grain refinement of this coating [13]. These results can be explained by the same mechanism: The epitaxial growth of the crystal facets is stopped because of the co-deposition of carbon which has a different chemical bonding (covalent) than Al₂O₃ (ionic); new nucleations have to occur to continue the deposition, which leads to the grain refinement.

5. CONCLUSION

Small amounts of AlCl₃ and BCl₃ added to the commonly used TiCl₄/H₂/CH₄ CVD gas mixture can strongly influence the layer growth and the grain size, while ZrCl₄ doping showed no influence. The differences in the influence on the grain size due to the various impurities can be explained by the differences in chemical bonding between the deposited impurity compounds and the TiC.

6. ACKNOWLEDGEMENT

The authors wish to thank Mitsubishi Materials Corporation for financial support and for permission to publish these results, as well as Mr. Yoshimura for his continued interest in this work.
