In neutron radiography some object details or domains of different composition that cause low variation of attenuation can be invisible. In the same time the macroscopic inhomogeneity domains (∼10^{-4} cm scale) could be visible using VSANS technique. The big sensitivity of this method is due to the large VSANS cross section under the conditions of high angular resolution (about 1 sec of arc). Detection of the second phase precipitates and corrosion products on aluminium alloy are the examples of the method advantages. The second phase could be revealed at the level of 10^{-2}-10^{-3} volume fraction. The corrosion product layer of ∼0.1 cm thickness could be observed. VSANS could be used as sensitive method of nondestructive testing.

Precipitation of the second phase causes the durability loss of the materials and products. For instance, the presence of macro inclusions in the defendant details of the engine or hidden corrosion in the honeycomb panels could be the reason for heavy accidents of the aircraft. Problem of detection of macro inclusions can be solved by using the method of very small angle neutron scattering (VSANS) with the second of arc angular resolution. Aim of the present paper is to determine the sensitivity of VSANS for the detection of macro inclusions or their aggregations in the materials for example the corrosion products and second phase precipitates in aluminium alloy.

Angular deviation of neutrons as a result of diffraction at the sphere of radius r is defined by the equation

\[ \Delta \phi = \frac{3}{2} \frac{\lambda}{(2\pi r)} \]  
(1)

where \( \lambda \) is the wavelength. So for the detection of big inclusions (\( r > 10^{-4} \) cm) the required angular resolution is of the order of angular second (12" for \( r = 1 \times 10^{-4} \) cm and \( \lambda = 2.3 \) Å), which is characteristic for VSANS [2,3].

Cross section of diffraction at the spherical inclusion amounts to [1]

\[ \sigma_{di} = 2\pi r^4 \lambda^2 (N_b^i N_m^b m^b)^2 \]  
(2)

where the values of scattering amplitude density \( (N_b)^{i,m} \) correspond to the material of inclusion and metal respectively. Small angle scattering is usually considered as a weak process, but it is not so for macro inclusions. The reason is that the diffraction cross section grows according to the law \( \sigma_{di} \sim r^4 \), but the attenuation cross section grows as the volume of particle, \( \sigma_{a} \sim r^3 \). So the ratio \( \sigma_{di}/\sigma_{a} \sim r \) grows as particle size.

For \( \text{Al}_2\text{O}_3 \) \( (N_b = 5.86 \times 10^{10} \text{ cm}^{-2}) \) sphere the diffraction cross section for thermal neutrons is close to the attenuation cross section \( \sigma_{a} = (4/3)\pi r^3 N(2\sigma_{Al}^2 + 3\sigma_{O}^2) \) for small precipitates, and for big ones \( (r = 10^{-4} \) cm) the ratio \( \sigma_{di}/\sigma_{a} \) amounts to 300 (fig.1). So the small angle scattering at macro inclusions should be a strong process.

Diffraction attenuation of the beam after the pass t in the metal with volume fraction of precipitate \( \xi \) with uniform distribution is defined by the number of particles in unit volume \( n_i = \xi/(4\pi r^3/3) \):

\[ T_{di} = \exp(-n_i \sigma_{di}) = \exp[-(3/2)\xi r^2 (N_b^i N_m^b m^b)^2 t] \]

Let’s estimate the effect of small angle diffraction for $\text{Al}_2\text{O}_3$ and $\text{CuAl}_2$ precipitates in Al ($N_{pm}b_m=2.1\times10^{10}\text{cm}^{-2}$, $N_{bp}=3.16\times10^{10}\text{cm}^{-2}$) for $t=1\text{cm}$ for thermal and cold neutrons. Usual attenuation doesn’t exceed the limit of contrast sensitivity of neutron radiography (2-3%) for $\xi=10^{-2}$. So the domains of precipitation could not be revealed by both neutron radiography and transmission measurement without high angular resolution. Estimation of the diffraction attenuation according to (3) shows that the VSANS sensitivity to the volume part of precipitate amounts to $10^{-3}-10^{-2}$ for thermal neutrons and $10^{-4} - 10^{-3}$ for cold neutrons (fig.2).

For not compact layer of the corrosion products the diffraction attenuation is defined by the cross section of single particle

$$\sigma_a=2\pi^2\lambda^2(N_{p}b_p)^2$$ (4)

where subscript $p$ corresponds to the corrosion product and the relative density $\eta$:

$$T_{ap}=\exp\left[-(3/2)\eta\lambda^2(N_{p}b_p)^2\right]$$ (5)

Estimation of the beam attenuation according to (5) for the possible corrosion products $\text{Al(OH)}_3$ and $\text{AlO(OH)}$ as a function of the layer thickness with $r=1\times10^{-4}\text{cm}$ and usual attenuation shows that the use of VSANS increases the sensitivity for the layer thickness by 1-2 orders of magnitude (fig.3). In the case of $\text{AlO(OH)}$ VSANS must reveal the monolayer of micron particles at the surface.

Experiment was carried out by using the double crystal spectrometer setup (fig.4a) at the STOIK spectrometer [4] in RSC KI. Angular resolution was about 1" for $\lambda=2.3\text{A}$ and the width (FWHM) of the reflection curve 5" (fig.4b). The sample was the duralumin plate (150x40x1.4mm$^3$) after the corrosion treatment, after which a half of the plate had been covered with a thin corrosion layer. Variation of the beam path length inside the sample was done by inclination of sample at the small angle $\alpha$ to the beam (in this case $t_{eff}=t/(\sin\alpha)$). Scattering curves (fig.4c,d) and the curve of scanning the sample by narrow beam (3mm width) at the peak position of scattering curves (fig.4e) were taken. The image of the corrosion spot was obtained by the X-ray film with Gd converter placed in front of the detector (fig.4f).

A narrow peak of the same width as for the reflection curve without a sample could be observed at the scattering curve for the initial alloy (fig.4c), which is applied to the more wide peak with the width of about 20" and nearly the same area. It means that half of neutrons is scattered to the angle of 10" and others are not diffracted, so $T_{d}=0.5$. This leads to the precipitate size of $1.3\times10^{-4}\text{cm}$. Assuming that small angle scattering in the duralumin is due to the intermetallic precipitate $\text{CuAl}_2$, the volume part of it amounts to $\xi=0.09$. In the case of presence of oxide precipitate their total fraction is less and equals to several percent. Experimental data shows that the effect of small angle scattering could be observed for $\xi<10^{-2}$, in accordance with the results of study of the hydride precipitation in Nb [5].

For the corroded part of the sample the diffraction attenuation in the corrosion layer and in alloy itself are approximately equal (fig.4e), and the shape of the curve is close to that of the sample without corrosion. It means that the size of corrosion product particles is close to $1\times10^{-4}\text{cm}$. Thickness of the layer was measured as $(7-10)\times10^{-4}\text{cm}$ from usual attenuation. The expected diffraction attenuation for this thickness is less than 5% for $\text{Al(OH)}_3$ and nearly 40% for $\text{AlO(OH)}$ according to (5). So we can decide that the composition of layer is close to $\text{AlO(OH)}$. As the diffraction attenuation in this layer is much bigger than the minimal measurable
value we can expect that the minimal detectable layer approaches $10^{-4}\text{cm}$ in accordance to estimation results (fig.2).

Radiograph of the corrosion spot taken at $\alpha=10^\circ$ shows its irregular shape and thickness by variations of contrast (fig.4f). Zones of inhomogeneous density of precipitate and voids can be also visualized [8].

Results of this work as well as [6,7] confirm in principle the possibility of detection of precipitates and corrosion products in alloys by means of VSANS. Real perspective of the VSANS based method of nondestructive testing is not obvious and is defined by several factors, such as the use of reactor and transportation expenses. The most simple task could be the control of a product as a whole by gauging the attenuation and determination of average density of precipitate or corrosion layer thickness. It can be solved not only using the double perfect crystal setup but also using highly collimated cold neutron beams available at neutron guides.

The work is supported by the Russian Foundation for the Basic Research.
