Abstract: Under the action of a periodically modulated laser beam the development of a convective liquid motion due to creation of surface tension gradients counteracts the heat conductivity flux. This autoblocking effect manifests itself in the abrupt changes of the phase and the amplitude of the excited capillary wave.

1. INTRODUCTION

When a laser beam is incident on an absorbing liquid a deformation of the surface can be observed at the focal spot [1-3]. At moderate laser intensities of about several W/cm² this deformation was shown to be the result of the development of liquid motion [4]. The reason is that the heating of a liquid surface leads to the creation of surface tension gradients which in turn launch the liquid flow producing the so called Marangoni motion. In the case that a modulated cw laser beam is used, periodical perturbations of the liquid surface arise, which at frequencies larger than about 10 Hz propagate along the surface in the form of capillary waves. The excitation of the capillary waves by a modulated laser beam has been observed previously [2]. However this is the first time that the detailed mechanism of laser induced capillary wave generation is being studied. In particular the determination of the dependence of the capillary wave amplitude on the laser intensity is of interest. So far the existing theory is incomplete [5] since it does not take into account the development of the liquid motion. In the present work we use a wide range of laser intensities and demonstrate that already at moderate intensities surface deformation with Marangoni motion is a dominant excitation mechanism leading to abrupt changes in the capillary wave amplitude and phase.

2. EXPERIMENTAL APPARATUS

In the experiments an Ar⁺ laser beam was on-off modulated with a stabilized chopper and was focused on the surface of a strongly absorbing dye solution (LDS 751 dissolved in ethylene glycol at a concentration of 1.25 g/L). The optical absorption at the laser wavelength of λ=515 nm was measured to be α=70 cm⁻¹. The capillary waves and the

3. RESULTS

In our experiment we measure the changes of the deflection angle of the probe beam reflecting off the observation point as the capillary wave passes through. The sensitivity of the registration scheme for surface inclinations of the liquid was about 80 V/degree. Fig. 1 depicts the observed signal amplitude versus laser intensity. The radius of the focal spot was $a=0.7$ mm, and the observation point monitored by the probe beam was a distance $d=5$ mm away from the focal spot. At low intensities the signal of the capillary waves shows linear behavior [5]. However at an intensity of about $I_i=1.3$ W/cm$^2$ an abrupt increase in the capillary wave signal occurs together with an increase of the average surface deformation signal. This is the threshold intensity for the onset of Marangoni motion. For laser intensities between $1.5 < I < 2.5$ W/cm$^2$ a change of the phase of the capillary wave signal of about 80 degrees (for $f=40$ Hz) was also observed. Similar results were observed under a variety of different experimental conditions when varying the radius of the focal spot between $a=0.5$ and 0.7 mm, the depth of the liquid layer between $h=2$ and 14 mm, and the modulation frequency between $f=16$ and 60 Hz.

4. THEORY

A detailed nonlinear model of the Marangoni motion was developed taking into account also the pulsations of this motion due to the modulation of the laser beam. According to this model a sudden increase of the temperature relaxation time near the threshold intensity $I_i$ takes place. At this intensity the heat flux from the absorption region due to the heat...
conductivity of the liquid is reduced by a backward heat transfer caused by the occurrence of a counterflow of the liquid. Such an *autoblocking* effect of the heat flux in the system leads to an abrupt temperature increase and to changes in the amplitude and phase dependences of the signal observed.
