HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Quantum efficiency and metastable lifetime measurements in ruby 
(Cr$^{3+}$:Al$_2$O$_3$) via lock-in rate-window photothermal radiometry

The newly developed photothermal detection technique of rate-window infrared radiometry has been 
applied to the measurement of the metastable state de-excitation parameters of a ruby laser rod. 
By applying the photothermal lock-in rate-window concept, the radiative lifetime and quantum 
efficiency of Cr$^{3+}$: Al$_2$O$_3$ have been measured with optimal signal-to-noise ratio (SNR) and simple, 
unambiguous interpretation from the extremum in the lock-in analyzer in-phase rate-window signal.

I. INTRODUCTION

In this work we introduced the recently developed technique of lock-in rate-window photothermal 
radiometry (PTR) [1] to perform accurate measurements of the non-radiative quantum efficiency, $\eta_{\text{NR}}$, in 
ruby. We used luminescence lock-in rate-window signals from a ruby sample to measure the metastable 
lifetime $\tau_{21}$ optically, with the photodiode signal being proportional to the metastable level population $N_2(t; \tau_{21})$. PTR rate-window signal analysis was based on a simple time-resolved PTR model for ruby.

2. TIME-RESOLVED PTR OF LASER MATERIALS

For a solid state laser medium exhibiting three-level dynamic behavior, such as Cr$^{3+}$: Al$_2$O$_3$, under the time-
gated square-pulse excitation of a rate-window type of experiment [1], the rate equation for level $|2\rangle$ is 
given by

$$
\frac{d}{dt} N_2(t) = N_1 W_R(t) - \frac{N_2(t)}{\tau_{21}},
$$

where

$$
\tau_{21} = \frac{1}{W_R + W_{\text{NR}}},
$$

with $W_R$ and $W_{\text{NR}}$ being the probabilities for radiative and nonradiative decay, respectively. In Eq. (1) it is 
assumed that $N_1$ is constant, a condition valid for sufficiently weak pumping of the ground state $|1\rangle$, 
which is also always heavily populated in a three-level laser medium. The pumping rate $W_R(t)$ to level $|3\rangle$ is 
given by

Article published online by EDP Sciences and available at http://dx.doi.org/10.1051/jp4:1994794
where $\tau_p$ is the square laser pulse duration. The solution to rate Eq. (1) under the initial condition $N_2(t = 0) = 0$ is

$$N_2(t; \tau_{21}) = \begin{cases} 1 - \exp(-t/\tau_{21}), & t \leq \tau_p \\ \exp(t/\tau_{21}) - 1 \exp(-t/\tau_{21}), & t \geq \tau_p. \end{cases}$$

As the result of the nonradiative decays in the optical medium, which include the relatively slow $|2> \rightarrow |1> + |3>$ decay preceded by the fast nonradiative $|3> \rightarrow |2>$ transition, the thermal power density in $J/cm^3$ released in the laser material is

$$A(t) = N_1 E_{32} W_p(t) + \left( \frac{\eta_{NR}}{\tau_{21}} \right) E_{21} N_2(t; \tau_{21}),$$

where

$$\eta_{NR} = \frac{\tau_{21}}{\tau_{NR}} = \frac{W_{NR}}{W_R + W_{NR}}.$$

The increase in the surface temperature of the laser medium can be monitored using infrared photothermal radiometric detection. For this purpose, the coupled heat diffusion equations in the sample (s), surrounded by two gaseous regions (air; (g)) can be written

$$\frac{1}{\alpha_s} \frac{\partial T_s(x,t)}{\partial t} - \frac{\partial^2 T_s(x,t)}{\partial x^2} = 0, \quad x \leq 0 \text{ and } x \geq L,$$

$$\frac{1}{\alpha_s} \frac{\partial T_s(x,t)}{\partial t} - \frac{\partial^2 T_s(x,t)}{\partial x^2} = \frac{A(t)}{k_s} \exp(-\beta_{31} x), \quad 0 \leq x \leq L,$$

where $\alpha_s$ is the thermal diffusivity of the $j$-th layer, $k_s$ is the solid thermal conductivity, and $\beta_{31}(\lambda)$ is the absorption coefficient of the optical medium (s) at the excitation wavelength and is proportional to the population of level $|1>$:

$$\beta_{31}(\lambda) = N_1 (W_{p0} E_{32} / I_0),$$

where $I_0$ in $W/cm^2$ is the incident laser intensity.

Equations (7a) and (7b) are subject to the usual temperature and heat flux continuity. Under thermally thick and optically thick conditions, realistic for PTR detection at early times:
the Laplace transforms of these equations can be explicitly inverted to yield the backscattered signal

\[ S_p(t) = C\tau_{21} \left\{ \begin{array}{ll}
(1 + Q) \left( t/\tau_{21} \right) - Q \left[ 1 - \exp(-t/\tau_{21}) \right], & t \leq \tau_p \\
(1 + Q) \left( \tau_p/\tau_{21} \right) - Q \left[ \exp(\tau_p/\tau_{21}) - 1 \right] \exp(-t/\tau_{21}), & t \geq \tau_p
\end{array} \right. \]

where

\[ C = \text{const.} \times (I_0 R\beta_{31} \alpha_s/k_s) ; Q \equiv \eta_{\text{NR}}(E_{21}/E_{32}) \]  

3. EXPERIMENTAL AND DISCUSSION

Experiments were performed with a cylindrical ruby sample, 6 cm in length and 1 cm in diameter [2]. The two flat surfaces were polished smooth, whereas the curved surface was rough and light scattering. Luminescence emitted through the curved side surface of the optically pumped ruby rod was filtered from excitation line photons and measured.

The in-phase (IP) luminescence rate-window signals were measured for three pulse durations \( \tau_p \): 1 ms, 4 ms, and 10 ms. The lock-in signal extremum was analyzed using explicit rate-window expressions, yielding the simple linear relationship:

\[ (T'_0)_{\text{max}} = 2.5681 \tau_{21} + 1.9973 \tau_p \]  

The range of \( \tau_{21} \) values obtained from all three \( \tau_p \) curves was

\[ \tau_{21} = 3.789 \pm 0.14 \text{ ms} \]

in excellent agreement with our earlier calculations using frequency-domain PTR [2].

The results of the rate-window PTR measurements on ruby are shown in Fig. 1a. The data points on this figure belong to two separate experimental runs and their low scatter is a measure of the excellent reproducibility of this technique. The lock-in IP signal maximum was analyzed using the \( \tau_{21} \) value obtained from the luminescence experiment. Figure 1b shows that for the range of \( \tau_{21} \) values obtained experimentally, the condition for the rate-window extremum, yields a simple, nearly linear dependence on \( Q \). In the range of experimentally expected \( Q \)-values (< 50%) with \( \tau_p = 6 \text{ ms} \), the relationship shown in Fig. 1b can be expressed numerically as

\[ (T'_0)_{\text{max}}/\tau_p = 0.361 Q + 1.397 \]

The linearity of the \( (T'_0)_{\text{max}}/\tau_p \) vs. \( Q \) relation improves with increased \( \tau_p \). From Figure 1b one thus obtains \( Q = 0.121 \). Using [3] \( E_{21} = 1.79 \text{ eV} \) and \( E_{32} = 0.62 \text{ eV} \) in the \( Q \)-defining expression, one obtains the value of non-radiative quantum efficiency:
This new value is in excellent agreement with $\eta_{NR} = 0.04$, the value calculated using the harmonically-modulated PTR phase in Ref. [2]. Note the greater standard deviation in the value $\eta_{NR} = 0.10 \pm 0.05$ reported by Quimby and Yen, [3]. The SNR of the rate-window IP signal, Fig. 1a, is superior to that of the PTR phase [2], as expected from theory [1], which makes the present value of $\eta_{NR}$ more reliable. This advantage in SNR of rate-window PTR becomes more pronounced with shorter $\tau_{21}$, for which the required probe modulation frequency range has very low thermal energy content.
