Institut für Physikalische Hochtechnologie e.V., PF 100239, 07702 Jena, Germany

Abstract. Directly coupled dc SQUID gradiometers on the basis of YBa$_2$Cu$_3$O$_{7-x}$ for unshielded NDE measurements are investigated. The influence of different SQUID layout parameters on the field sensitivity is shown. A sensitivity of 500 fT/(cm·Hz) is achieved with a baseline of 3.6 mm. A slit in an aluminium plate was detected in a demonstration of NDE in 1 cm depth with eddy current method.

1. INTRODUCTION

The ultimate sensitivity of SQUIDs to magnetic flux results not only in applications for exclusive purposes, but they are also established in biomagnetic measurements and emerging in non-destructive evaluation (NDE) [1-3]. Because of the high costs wider applications were restricted as long as liquid helium for cooling and especially shielded rooms to protect the SQUID from environmental disturbances were needed. The comparable cheap coolant liquid nitrogen used for devices made of high temperature superconductors raised new interest to apply SQUIDs in lower cost measurement systems, thus outside shielded rooms.

The purpose of our work is to develop high $T_c$ dc-SQUIDs for NDE of deep defects in the millimetre or centimetre range. The SQUIDs have to be able to operate without shielding in conventional electromagnetically disturbed environments.

NDE offers the possibility to use gradiometer structures which remain sensitive to near sources of magnetic fields (defects in the investigated material) and suppress external magnetic disturbances which are nearly homogeneous because of their long distance from the SQUID. Due to the skin effect in the materials to be investigated (steel or aluminium) NDE of deep defects demands a high field gradient sensitivity in the 1 or 10 Hz frequency range. This requires a low flux noise of the SQUID structure in this frequency range and a large effective area. Furthermore the baseline of the gradiometer should be comparable to the distance of the SQUID to the defects to achieve best sensitivity [4].

A large effective area can most easily be achieved with a large bare SQUID. However this way is restricted because of the SQUID inductance which should not exceed 100 pH at 77K [5]. For this reason it is advantageous to use a separate pickup coil having a large effective flux capture area. To avoid inductance mismatch between the SQUID and pickup coil it can be coupled to the SQUID via a multiturn spiral input coil. The SQUID is usually formed as a washer [6]. These complex structures have already been realised in high $T_c$ [7,8], but the fabrication is still difficult. Such devices usually exhibit substantial $1/f$ noise which is drastically enhanced in unshielded operation. This also holds for devices where SQUID and pickup coil with flux transformer are fabricated on separate chips and afterwards pressed together in flip chip configuration [9].
Therefore single layer devices are still attractive for SQUID designs. This can be a large washer that takes advantage of the flux focusing effect \[10\] without increasing the SQUID inductance. For magnetometers with this concept a good field resolution of 170 fT/√Hz down to frequencies of 1 Hz was achieved \[11\], but for gradiometers the slit in the washers would increase the inductance unacceptably. Another approach is to couple a large gradiometer pickup coil directly to the SQUID \[12-16\]. The SQUID as a galvanometer detects the current originated by the field in the pickup loop. Although for this layout the inductance mismatch between pickup coils and SQUID will be substantial, acceptable effective areas can be achieved. Field resolutions of such directly coupled magnetometers (or also called "galvanometers") of 26 fT/√Hz at 1 Hz are reported \[17\].

We investigated a directly coupled gradiometer SQUID. Its design will be described in section 2. In section 3 and 4 we report on the fabrication technology and obtained results for several gradiometers, respectively. Especially, first results in a NDE application will be presented.

2. DESIGN

The layout of the single layer parallel gradiometer SQUID is shown in Fig. 1. In the central line of the gradiometer loop there are four SQUIDs in series. To study the influence of the SQUID inductance on the performance of the gradiometer, various SQUID loop sizes were used.

![View of a SQUID gradiometer (left) and a SQUID in the middle of the structure (right).](image)

The layout of this structure was designed in the following way: For a gradiometer the figure of merit is the field gradient sensitivity \( \partial B_{\text{min}}/\partial x \). It is supposed to result from the rms voltage noise \( \nu S_p \) of the SQUID

\[
\frac{\partial B_{\text{min}}}{\partial x} = \frac{2\sqrt{S_B}}{b} = \frac{2\sqrt{S_p}}{b A_{\text{eff}} V_\phi}
\]

where \( \nu S_p \) is the rms magnetic field noise in each pickup loop with an effective area \( A_{\text{eff}} \), \( b \) is the gradiometer baseline, and \( V_\phi = A/\partial \Phi \) is the flux-to-voltage transfer function. Taking the Josephson junction resistance as the main noise source, thus neglecting critical current fluctuations and flux noise of poor quality films, we have

\[
S_p = 16k_B T R
\]
with $R$ the junction resistance and $T$ the operation temperature [18]. $V_\phi$ degrades with temperature in accordance with [19]

$$V_\phi = \frac{4eIR}{\Phi_0} \exp\left[-3.5\pi^2 \frac{k_BT \cdot L_{sq}}{\Phi_0^2}\right]$$

where $\beta=2L_{sq}I_c/\Phi_0$ is the SQUID parameter, $L_{sq}$ the SQUID inductance, $I_c$ the critical current of one Josephson junction, and $\Phi_0$ the flux quantum.

So, to get a low magnetic flux noise the junctions should have a high $IR$ product, and the SQUID should have a low inductance. $L_{sq}$ and $I_c$ on the other hand must be balanced to have $\beta$ not much larger than 1 [20]. Additionally the influence of the SQUID inductance on the effective area

$$A_{eff} = \frac{kL_{sq}}{2A_{pu}^{\cdot}\left\{2kL_{sq} + L_{pu}\right\}}$$

must be taken into account, where $A_{pu}$ and $L_{pu}$ are the pickup area and the inductance of one gradiometer loop, respectively. $k<1$ represents the part of the SQUID loop where the current from the pickup loops flows. The inductance of the rectangular SQUID was estimated with three different formulas: for coplanar lines [21], for a round washer, and for a quadratic washer [6], where the rectangular SQUID hole was approximated by a quadratic or a round one having the same area. Contributions of kinetic inductances were also included assuming a London penetration depth of 300 nm. The results of the three methods agree within 10%. The optimisation of $A_{eff}$ by given $L_{sq}$ and chip size is reported in [22].

The SQUID structures are designed for 10x10 mm$^2$ substrates. The pickup loops have an outer diameter of 4 mm. Their line width of 400 $\mu$m was chosen to be sure that the superconducting loop should be able to carry the screening current originated by moving the SQUID unshielded in the earth magnetic field. The gradiometer baseline $b$ is 3.6 mm. The SQUID inductance is built by a U-form strip of 20 $\mu$m width having a 10 $\mu$m slit. The length $l$ of this slit was varied to minimise the magnetic field noise $\sqrt{S_\phi}$. Figure 2 shows the calculated dependence of $\sqrt{S_\phi}$ on $l$ for different critical currents $I_c$ of the junctions assuming the $IR$ product to be 100 $\mu$V. The values of the SQUID parameter $\beta$ are shown too.

To be able to use a SQUID which is near the optimum performance for a given $I_c$ the four SQUIDs got hole lengths of 40, 80, 120 and 160 $\mu$m.

Fig. 2. Field noise and SQUID parameter $\beta$ calculated for $I_c = 20$ (lower-), 40, 80, and 160 $\mu$A (upper curve).
3. FABRICATION

The SQUID structures were realised using symmetrical $24^0$ (100) SrTiO$_3$ bicrystals. A 100 nm thick YBa$_2$Cu$_3$O$_{7-x}$ layer was deposited, either by hollow cathode sputter deposition (HC) or by pulsed laser deposition (PLD). The critical current densities at 77 K for the HC and PLD layers are up to $2 \times 10^6$ A/cm$^2$ and $3 \times 10^6$ A/cm$^2$, respectively. Directly after YBa$_2$Cu$_3$O$_{7-x}$ deposition a 100 nm thick gold layer was evaporated. After removing gold and YBa$_2$Cu$_3$O$_{7-x}$ film at the substrate edges the SrTiO$_3$ was shortly etched with diluted HF to make the grain boundary visible. Next YBa$_2$Cu$_3$O$_{7-x}$ and gold were patterned using Ar ion beam etching through a photoresist mask. The width of the junctions was about 7 μm.

4. RESULTS

All results were achieved at 77 K. The Josephson junctions of the SQUIDS showed $I_R$ products of (70...150) μV for the HC structures and (180...240) μV for the PLD structures. Critical currents of the junctions ranged from (26...153) μA for HC and (95...330) μA for PLD structures. Because of the large critical currents only the smaller SQUID loops with 40 and 80 μm length could be used. For the other SQUID  $\beta$ was too large and with that the voltage modulation too small to get stable working regimes. In the following the results of two HC and two PLD structures will be presented. The $V(I)$- and $V(\Phi)$- curves as well as noise spectra were measured for all SQUIDs. Noise measurements were performed in flux-locked loop at a bias current yielding maximum $V_\phi$. The flux modulation frequency was 125 kHz. Additionally bias reversal with 4 kHz could be used. Shielded measurements were performed with two concentric mu-metal cylinders. Fig. 3 shows examples of noise spectra.

To determine the magnetic field sensitivity $\nu B_g$ and the effective and parasitic areas the SQUIDs were used without shielding in a plastic cryostat. $A_{\text{eff}}$ was determined by changing the distance of a small coil outside the cryostat to the SQUID. $A_{\text{par}}$ as a value of the unwanted response of the gradiometer to homogeneous fields was measured in the field of a large Helmholtz coil system having a deviation from homogeneity $< 2 \times 10^{-4}$.

The parameters of the measured SQUIDs are summarised in Table 1. The values of the critical current are obtained from the $V(I)$ characteristics taking into account the thermal noise rounding.

The results show that except for SQUID #3 reasonable good magnetic flux noise $\sqrt{S_\Phi}$ could be achieved. Without shielding the noise level increases approximately by one order of magnitude. Best field resolution showed SQUID #2. Here the low critical current allowed to use a larger SQUID loop that gives a larger effective area. To take further advantage of the larger SQUID loops the junction width should be reduced to about 1 $\mu m$ to have small critical currents and still a high $I_R$ product. The large parasitic areas in the sensitive direction of the gradiometer are originated by the magnetometer structure of the SQUID itself.

With SQUID #3 first eddy current NDE measurements were performed. Fig. 4 shows the experimental setup. We tried to detect a 4 cm long, 1 mm wide slit made in a 4 mm thick 400 x 400 mm² plate of 99.5% aluminium. The plate with the slit was placed at different distances to the SQUID and was covered with other Al plates. A straight wire carrying an ac current was used for excitation of eddy currents. In Fig. 5 the results of the measurements are given which show the principal possibility to detect defects in various depths with our high $T_c$ SQUID gradiometer.

Fig. 4. Experimental setup for eddy current NDE of a phantom object, i.e., an aluminium plate with a slit.
Summary

An integrated single layer YBCO SQUID gradiometer was developed and manufactured for unshielded non-destructive evaluation of deep defects in metal. A sensitivity of 500 fT/cmHz$^{1/2}$ was achieved. A demonstration of NDE with the eddy current method shows the possibility to detect a slit laying under the surface of an Al plate.

This work was partially supported by the German BMBF in the HOTRONIK program.
