Abstract: The behaviours of as-received and recrystallised (homogenised) MA 956, an Al-containing Cr-rich ferritic stainless steel, aged at 475 °C for up to 2900 hours have been investigated. Atom probe microanalysis of the decomposition products revealed that Al did not partition significantly to the Fe-rich phase after ≈600 hours ageing, contrary to thermodynamic predictions. Ageing to 2900 hours, however, resulted in partitioning. Further thermodynamic analysis showed that the chemical potential of Al in the Cr-rich α' phase increased more rapidly at later stages of phase separation. The wavelength and amplitude of decomposition were found to be significantly larger in aged as-received material compared to aged homogenised material, consistent with coarsening accelerated by the enhanced solute mobilities associated with the highly-dislocated as-received material. Ti- and Si-rich precipitates were found at the α/α' interfaces at later stages of ageing.

1. INTRODUCTION

The hardening of binary Fe-Cr alloys during ageing at low temperatures (so-called ‘475 °C embrittlement’) has been shown, by atom probe field ion microscopy (APFIM), to be due to the spinodal decomposition of the supersaturated solid solution into Fe-rich α and Cr-rich α' phases [1]. Additionally, it has been shown that similar decomposition occurs in the Cr-enriched ferritic phase of duplex stainless steels and in single-phase Fe-Cr based ternary and higher order alloys [2-14]. The addition of alloying elements (Co, Ni, Si, Mo) to the binary Fe-Cr system has been shown to affect the kinetics and products of the decomposition process [2-14]. These alloying elements themselves partition preferentially between the α and α' phases, as the decomposition reaction proceeds. The driving force for their partitioning arises from the reduction in the free energy of the system. However, it has been shown recently [15] that Al does not appear to partition preferentially to the Fe-rich α phase, as predicted thermodynamically, during ageing of up to ≈600 hours at 475 °C of MA 956, an Al-containing Cr-rich oxide-dispersion-strengthened (ODS) ferritic stainless steel produced by mechanical alloying. In the as-received state, the microstructure is characterised by all the features of cold-deformation: ultrafine (sub-micrometer) convoluted grains elongated in the working direction (=0.2 × 4 μm) and a high dislocation density [16]. Subsequent heat-treatment of as-received material leads to primary recrystallisation, producing a very coarse-grained microstructure (=2 × >40 mm) similar to that of a directionally-recrystallised microstructure. The aims of this work were to investigate the partitioning behaviour of Al during phase separation of MA 956 when the α and α' domains are expected to be in thermodynamic equilibrium and to investigate the effects of microstructure on the decomposition process.
2. EXPERIMENTAL

The alloy, of nominal composition Fe-20Cr-4.5Al-0.5Ti-0.01C-0.5Y$_2$O$_3$ (wt.%) or Fe-20.2Cr-8.8Al-0.55Ti-0.044C (at.%, ignoring Y$_2$O$_3$ addition), was supplied by INCO Alloys (Hereford, UK) in an unrecrystallised (as-received) state. It was fabricated by mechanical alloying of three primary powders (elemental iron, pre-alloyed metallic alloys and yttria) in a vertical water-cooled attritor. Consolidation of the resultant alloy powder was by canned extrusion at 1000 °C and subsequent rolling.

Material for examination was machined from the core region of the as-received bar. Homogenisation treatment of 24 hours at 1300 °C resulted in full recrystallisation. Subsequent isothermal ageing at 475 °C was conducted for as-received and for homogenised material for times between 1 and 2900 hours. The final heat treatment was terminated by iced-water quench. Specimens for APFIM analysis were prepared by standard two-stage electropolishing of blanks (15 × 0.23 × 0.23 mm) machined from the core of the bulk heat-treated specimens, parallel to the extrusion direction [15].

The atom probe characterisations were performed using a reflectron-based time-of-flight atom probe (Applied Microscopy Ltd. APFIM 220 [17]) equipped with a position-sensitive detector (PSD) (Kindbrisk Ltd. PDA60/L [18]) for position-sensitive atom probe (PoSAP) analysis. Atom probe analysis was conducted between temperatures of 50 and 80 K, employing a pulse fraction of 20% at a pulse repetition rate of 200 Hz. PoSAP analysis was conducted at 30 K, at a pressure ≤7×10$^{-9}$ Pa, at a pulse fraction of 15% and a pulse repetition rate of 200 Hz. Hydrogen was not gated from detection so incorrect positioning of second ions was discarded. In the atom probe mass spectra, the peak at $m/n = 25.0$ was assigned to $^{50}$Cr$^{2+}$ since the natural isotopic abundance of $^{50}$Ti$^{2+}$ is small (5.34 at.%). The peak at $m/n = 27.0$ was assigned to $^{54}$Fe$^{2+}$ since the natural isotopic abundance of $^{54}$Cr$^{2+}$ is small (2.38 at.%) and Al was deemed to evaporate as $^{27}$Al$^{2+}$ and $^{27}$Al$^{3+}$ only. Silicon was deemed to evaporate as Si$^{2+}$ only; hydrides of Al were ignored. All compositions quoted are in at.%.

3. RESULTS

3.1 Thermodynamic analysis

Table 1 shows the compositions of the equilibrium Fe-rich and Cr-rich phases at 475 °C, calculated employing the Fe and Scientific Group Thermodata Europe (SGTE) solution databases in ThermoCalc [19] and considering the equilibrium between α and α' only. The miscibility gap in the Fe-Cr binary system was defined and employs the thermodynamic description due to Andersson and Sundman [20]. The solvus temperature for MA 956 is calculated as 764 °C and 548 °C, employing the Fe and SGTE solution databases respectively. APFIM analysis of material aged at 560 °C for ≈7200 hours did not show evidence of phase separation (contrary to predictions employing the Fe database) and thus, the results calculated employing the SGTE solution database are potentially more reliable. It is seen that Al and Ti are predicted to partition strongly to the α phase.

Table 1: Calculated phase compositions at 475 °C. The mole fraction of the Cr-rich phase is 0.17 and 0.11, employing the Fe- and the SGTE solution databases respectively. $c_{\alpha}^\alpha/c_{\alpha'}^\alpha$ is the ratio of the concentrations of Al in the α and α' phases.

3.2 APFIM analysis

Composition depth profiles for aged recrystallised material are shown in Figure 1. The Cr composition depth profiles for aged materials clearly show the formation of the two-phase $\alpha+\alpha'$ microstructure. Compositional analysis of the two phases formed on ageing both the recrystallised and the as-received material, as delineated from Cr ladder diagrams, is shown in Table 2. The mole fraction $V^\alpha$ of the Cr-rich $\alpha'$ phase was determined from the compositional data. Note that the overall Cr and Al contents differ slightly from the nominal for material aged 598 hours, possibly as a result of preferential evaporation effects at the compromised temperature of analysis.

![Figure 1: Composition depth profiles for solute species in MA 956. Block size is 50 ions. Depth of analysis = 35 nm.](image)

Horizontal dashed lines show the average solute contents and 95% confidence intervals. (a) Recrystallised MA 956 aged at 475 °C for 588 hours. The supersaturated solid solution has decomposed into Fe-rich $\alpha$ and Cr-rich $\alpha'$ domains. The vertical dashed lines show some of the $\alpha/\alpha'$ interfaces. (b) Recrystallised MA 956 aged at 475 °C for 2900 hours. Both the wavelength $\lambda$ and the amplitude $\Delta c$ of decomposition have increased. Note Ti- and Si-rich phases near the $\alpha/\alpha'$ interfaces.

Table 2: Measured phase compositions of aged MA 956. The mole fraction $V^\alpha$ of the Cr-rich phase is $\approx 0.6$ and $\approx 0.5$ after 588 hours and $\approx 0.2$ and $\approx 0.15$ after 2900 hours for the aged homogenised and aged recrystallised material respectively. $c_{Al}^\alpha/c_{Al}^{\alpha'}$ is the ratio of the concentrations of Al in the $\alpha$ and $\alpha'$ phases. All compositions are in at.%.
The amplitude $A_c$ of decomposition was determined by both the $P_a$ method [21] and by square-wave modelling of the measured composition profile [22]. The wavelength $\lambda$ of decomposition was determined from the autocorrelation function [21]. An estimate of the depth analysed was made using a method described previously [23]. Ageing recrystallised MA 956 to 2900 hours leads to a coarser scale of decomposition ($\lambda = 5$ nm) as compared to recrystallised material aged to 598 hours ($\lambda = 1.3$ nm). Additionally, the amplitude of the Cr composition fluctuations increases with time ($A_c=0.25$ and 0.24 after 598 hours, increasing to $A_c=0.47$ and 0.40 after 2900 hours, employing the $P_a$ and square wave models respectively), consistent with spinodal decomposition. Ageing as-received MA 956 to 2900 hours leads to a coarser scale of decomposition ($\lambda = 8$ nm c.f. $\lambda = 5$ nm after 598 hours ageing). The amplitude of the Cr composition fluctuations also increases with time ($A_c=0.36$ and 0.32 after 598 hours, increasing to $A_c=0.58$ and 0.55 after 2900 hours, employing the $P_a$ and square wave models respectively). The estimated wavelengths and amplitudes of decomposition are significantly greater in as-received material than in recrystallised material for a given ageing treatment. Contingency tables [24] did not suggest significant partitioning of Al from the Cr-rich phase after ageing for 598 hours, when compared to homogenised material [15]. Partitioning of Al was evident for material aged for 2900 hours [25].

The composition depth profiles for recrystallised material aged for 2900 hours (Figure 1) additionally reveal the presence of Ti- and Si-enriched particles, the measured compositions of which are shown in Table 3. Similar particles were found in as-received material aged for 2900 hours. No such particles were detected after 598 hours ageing in either recrystallised nor as-received material. The precipitates are apparently located at the interface between the Fe-rich $\alpha$ and Cr-rich $\alpha'$ phases.

Table 3: Measured compositions of Ti-rich phases in homogenised MA 956 aged for 2900 hours at 475 °C. It is expected that simultaneous sampling of the decomposed matrix and the small Ti-rich precipitates will dilute their compositions.

3.3 PoSAP analysis

Figure 2 shows PoSAP atom distributions for Cr, Al and Ti in recrystallised MA 956 aged for 2900 hours at 475 °C. While decomposition of the matrix is evident from the Cr atom distribution, little partitioning of Al to the Fe-rich $\alpha$ phase is evident. Ti-rich precipitates are located at $\alpha/\alpha'$ interfaces: compositional analysis of the precipitates yields $11.6±1.4$ Ti-$23.3±1.8$ Al-$17.7±1.6$ Cr-$47.4±2.1$ Fe (at.%). PoSAP data suggests a higher Ti content than that obtained by APFIM analysis - note that the higher Al content may include a contribution due to Si which may not be resolved from the mass spectra. The precipitate number density may be estimated as $1±0.3×10^{24}$ m$^{-3}$. 
Figure 2: PoSAP atom distributions for solute species (Cr, Al, Ti) in recrystallised MA 956 aged for 2900 hours at 475 °C. Each dot corresponds to the identification and positioning of a single ion. Analysed volume =14 nm diameter × 20 nm depth.

4. DISCUSSION

APFIM analysis of phase-separated MA 956 revealed insignificant partitioning of Al after ageing recrystallised material for 598 hours at 475 °C. Ageing to 2900 hours was accompanied by partitioning of Al to the Fe-rich α phase. Figure 3 shows the chemical potential $\mu_{Al}^{\alpha'}$ of Al in the Cr-rich α' phase as a function of Cr partitioning only, employing thermodynamic data from the SGTE solution database [19]. It is seen that $\mu_{Al}^{\alpha'}$ increases more rapidly when $\Delta c \geq 0.25$, consistent with the observation of insignificant partitioning of Al after ageing at 475 °C for 598 hours when $\Delta c = 0.25$. Thus, it appears that the partitioning of Al commences when there exists a sufficient driving force i.e. at later stages of phase-separation when the chemical potential of Al in the two phases is sufficiently different. This contrasts with the behaviours of Co and Ni: Co was observed to have partitioned at all stages of decomposition in Fe-Cr-Co alloys [4, 6] while Ni was observed to have partitioned significantly in Fe-45Cr-5Ni (at.%) after ageing for 500 hours at 500 °C [13], presumably since their driving forces for partitioning are sufficiently high at these stages of decomposition.

Figure 3: Chemical potential $\mu_{Al}^{\alpha'}$ of Al in the Cr-rich α' phase as a function of the amplitude $\Delta c$ of Cr partitioning, employing thermodynamic data from the SGTE solution database in ThermoCalc (19).
The wavelength and amplitude of decomposition were found to be significantly larger in aged as-received material compared to aged homogenised material, consistent with coarsening accelerated by the enhanced solute mobilities associated with the highly-dislocated as-received material.

The Ti- and Si-rich precipitates apparently form in a similar manner to G-phase precipitates (model based on Ni16Si7Ti6 and in which Cr, Fe, Mo, Mn, V, Nb, Ta, Hf and Zr may substitute for Ti and Ni) found during ageing of supersaturated Fe-Cr based ferrites [5, 8, 26-28]. Note that MA 956, however, is a Ni-free alloy. G-phase precipitates form at the α/α′ interfaces at later stages of decomposition. Further analysis of the precipitates in MA 956 is on-going.

5. CONCLUSIONS

Phase separation during ageing of MA 956 at 475 °C resulted in the formation of Fe-rich α and Cr-rich α′ domains. Insignificant partitioning of Al to the Fe-rich phase was observed after ageing for 598 hours, contrary to thermodynamic predictions. Ageing for 2900 hours resulted in coarsening of the microstructure, increased amplitude of decomposition and Al partitioning. Thermodynamic data showed that the chemical potential of Al in the Cr-rich α phase increased more rapidly for later stages of phase separation: Al only partitions when a sufficient driving force arises as a result of phase decomposition of Cr in Fe. The partitioning behaviour of Al contrasts with those of Co and Ni in Fe-Cr based alloys. The wavelength and amplitude of decomposition were found to be significantly larger in aged as-received material compared to aged homogenised material. Ti- and Si-rich precipitates were found at the α/α′ interfaces at later stages of ageing.
