Abstract

MACHINE LEARNING TO PREDICT IMPULSE CONTROL DISORDERS IN PARKINSON’S DISEASE

by Johann Faouzi

Impulse control disorders are a class of psychiatric disorders characterized by impulsivity. These disorders are common during the course of Parkinson’s disease, decrease the quality of life of subjects, and increase caregiver burden. Being able to predict which individuals are at higher risk of developing these disorders and when is of high importance.

The objective of this thesis is to study impulse control disorders in Parkinson’s disease from the statistical and machine learning points of view, and can be divided into two parts. The first part consists in investigating the predictive performance of the altogether factors associated with these disorders in the literature. The second part consists in studying the association and the usefulness of other factors, in particular genetic data, to improve the predictive performance.

In the first chapter, we present Parkinson’s disease and impulse control disorders, review the literature on impulse control disorders in Parkinson’s disease, introduce the main concepts of machine learning, and describe the databases from which we obtained data and the software used to analyze these data. In the second chapter, we investigate the predictive performance of several machine learning algorithms using features that have been associated with impulse control disorders in Parkinson’s disease. In the third chapter, we investigate the association between impulse control disorders in Parkinson’s disease and genetic risk scores for a broad range of phenotypes. In the last chapter, we investigate different approaches to integrate static data in recurrent neural networks and evaluate their predictive performance in the use case of predicting impulse control disorders in Parkinson’s disease, with genetic data used as static data.

Across these works, we highlight the importance of using machine learning algorithms, cross-validation and replication cohorts to unbiasedly estimate the predictive power of known and putative risk factors of impulse control disorders in Parkinson’s disease.
Les troubles du contrôle de l’impulsivité sont une classe de troubles psychiatriques caractérisés par des difficultés dans la maîtrise de ses émotions, pensées et comportements. Ces troubles sont courants dans la maladie de Parkinson et associés à une baisse de la qualité de vie des patients ainsi qu’à une augmentation de la charge des aidants. Pouvoir prédire quels sont les sujets les plus à risque de développer ces troubles et quand ces troubles apparaissent est de grande importance.

L’objectif de cette thèse est d’étudier les troubles du contrôle de l’impulsivité dans la maladie de Parkinson à partir des approches statistique et de l’apprentissage automatique, et se divise en deux parties. La première partie consiste à analyser la performance prédictive de l’ensemble des facteurs associés à ces troubles dans la littérature. La seconde partie consiste à étudier l’association et l’utilité d’autres facteurs, en particulier des données génétiques, pour améliorer la performance prédictive.

Dans un premier chapitre, nous présentons la maladie de Parkinson et les troubles du contrôle de l’impulsivité, effectuons une revue de la littérature sur les troubles du contrôle de l’impulsivité dans la maladie de Parkinson, introduisons les principaux concepts de l’apprentissage automatique et présentons les bases de données sur lesquelles nous avons travaillé et les logiciels utilisés pour analyser ces données. Dans un deuxième chapitre, nous étudions la performance prédictive de plusieurs algorithmes d’apprentissage automatique en utilisant comme variables d’entrée les facteurs associés aux troubles du contrôle de l’impulsivité dans la maladie de Parkinson. Dans un troisième chapitre, nous étudions l’association entre les troubles du contrôle de l’impulsivité dans la maladie de Parkinson et des scores de risque génétique pour un large panel de phénotypes. Dans un dernier chapitre, nous étudions différentes approches d’intégrer des données statiques dans des réseaux de neurones récurrents et évaluons leur performance dans le cas de la prédiction des troubles du contrôle de l’impulsivité dans la maladie de Parkinson, en utilisant des données génétiques pour les données statiques.

À travers ces travaux, nous mettons en avant l’importance d’utiliser des algorithmes d’apprentissage automatique, des méthodes de validation croisée et des cohortes de réplication pour évaluer la puissance prédictive de facteurs de risque connus ou supposés des troubles du contrôle de l’impulsivité dans la maladie de Parkinson.
Remerciements

Je souhaite tout d'abord remercier mes directeurs de thèse, Olivier Colliot et Jean-Christophe Corvol, pour m'avoir donné l'opportunité d'effectuer ce doctorat. Je me trouvais à un moment de ma vie où je n'étais pas sûr de ce que je souhaitais faire, et je leur en serai pour toujours reconnaissant. Je les remercie pour leur encadrement et leur disponibilité, mais aussi pour m'avoir laissé la liberté d'avancer à mon rythme et de travailler sur d'autres projets pendant ma thèse.

Mes remerciements vont également à l'ensemble des membres du jury pour s'être intéressés à mon travail. Je tiens à remercier Marta Avalos et Mélanie Prague pour avoir accepté d'être examitrices, ainsi que Gérard Blau et Alexandre Gramfort pour avoir accepté d'être examinateurs. Je remercie tout particulièrement Christophe Ambroise et Franck Durif pour avoir accepté d'être rapporteurs et pour avoir suivi mon travail tout au long de ma thèse en tant que membres des comités de suivi.

Je remercie les différents membres des équipes cliniques avec qui j'ai travaillé, notamment Stéphanie Carvahlo et Carole Dongmo pour leur aide sur la base de données NS-Park. Je remercie tout particulièrement Samir Bekadar pour toute son aide sur le traitement des bases de données et des données génétiques. Je remercie également Lydia Chougar et Stépahne Lehéricy pour m'avoir permis de travailler sur un projet de classification automatique des syndromes parkinsoniens.

Je remercie bien évidemment tous les membres de l'équipe Aramis qui ont rendu cette thèse fort agréable. Je souhaite remercier Baptiste pour son encadrement et Ninon pour ses conseils. Je remercie notamment mes plus proches voisins : Vincent pour nos discussions matinales, et Tiziana et Giulia pour avoir essayé de m'apprendre l'italien sans grand succès. Je remercie également Elina, Adam et Simona pour les innombrables discussions. Je tiens à remercier en particulier Pascal (le plus gros fly de France) pour m'avoir fait perdre la raison un bon million de fois et des dizaines d'heures à cause du PvP pour son aide et pour les bons moments passés ensemble sur notre passion commune.

Enfin, je souhaite remercier l'ensemble de ma famille, en particulier ma sœur, pour leur soutien indéfectible.

Introduction

Context

Parkinson’s disease (PD) is a neurodegenerative disease with no cure to date. Besides its characteristic motor symptoms, numerous non-motor symptoms have been reported to occur in the course of the disease (Chaudhuri et al., 2006). A specific symptom has recently been increasingly acknowledged: impulse control disorders.

Impulse control disorders (ICDs) are a class of psychiatric disorders involving problems in the self-control of emotions and behaviors (American Psychiatric Association, 2013). They include pyromania, kleptomania, Internet addiction disorder and intermittent explosive disorder for instance. In Parkinson’s disease, the four most common impulse control disorders are pathological gambling, binge eating disorder, compulsive sexual behavior and compulsive buying disorder (Weintraub and Claassen, 2017).

Many factors have been associated with impulse control disorders in Parkinson’s disease (Grall-Bonnec et al., 2018). Socio-demographic factors (age of PD onset, sex), psychiatric comorbidities (anxiety, depression), sleep disorders, and PD medication have been associated with ICDs in PD among others. Dopamine agonists (DAs), a class of PD medication, have been the most strongly correlated with ICDs. Dopamine agonists still have their advantages as they delay the initiation of levodopa, another class of PD medication with its own adverse effects.

Impulse control disorders are associated with a decrease in quality of life, strained interpersonal relationships, financial distress, medical complications, and higher caregiver burden (Weintraub and Claassen, 2017). Prompt identification and treatment of the symptoms are usually imperative to improve the quality of life of the subjects. However, managing impulse control disorders implies that they are already present. Accurately predicting which subjects are at higher risk of developing these disorders and when they occur could allow for early management, decrease their negative impact, and potentially prevent their apparition.
Objective

The general objective of this thesis is to study impulse control disorders in Parkinson’s disease from the machine learning point of view, with a focus on their predictability. Despite the rise of machine learning, this approach has been little to not used in the context of ICDs in PD.

Our first objective is to study the how well ICDs in PD can be predicted by combining the factors reported in the literature. The known risk factors come from univariate association studies that do not take into account the other risk factors. Machine learning allows for learning from a set of features at once and thus leveraging information from all the factors. Using machine learning comes with specific methodological requirements to assess their predictive performance in an unbiased manner. These methods, such as cross-validation, are not always well-known in the medical field but are necessary not to report overly optimistic results. We describe and apply such methods in this application.

Our second objective is to investigate the genetic factors of ICDs in PD, as little is known about these risks. A few associations from candidate genes analyses have been reported, but these studies have not been replicated. On the other hand, genome-wide association studies (GWAS) investigate the combined risk of the whole genome by computing a genetic risk score (GRS), but none has been published on ICDs in PD. Instead of performing a GWAS, which requires a large sample size, we study the association between ICDs in PD and genetic risk scores of other phenotypes, for which large GWAS exist.

Contributions

Our contributions in the field of impulse control disorders in Parkinson’s disease are three-fold. First, we study the added value of combining the reported factors associated with ICDs in PD to predict them, by training machine learning algorithms using these factors as input. Second, we investigate the association between ICDs in PD and genetic factors for a broad range of phenotypes, including other psychiatric disorders. Third, we study how to integrate time-dependent features, such as clinical measurements, and time-independent information, such as socio-demographic and genetic factors, in predictive models, with an application in the prediction of ICDs in PD using recurrent neural networks.

Only two studies have reported a classification task of impulse control disorders in Parkinson’s disease (Erga et al., 2018; Kraemmer et al., 2016). However, both studies lack a replication cohort and have major methodological issues (lack of cross-validation, biased feature selection) that alter the trust in the reported predictive performance. We propose the first study evaluating in an unbiased manner the predictive performance
of several machine learning algorithms using known risk factors as input data. We investigate the use of five standard machine learning classification algorithms (logistic regression, support vector machines with linear and RBF kernels, random forest and gradient tree boosting) and recurrent neural networks to predict the presence or absence of ICDs for a given patient at their next visit. In order to make the variable-length sequences of visits suitable as input data for the standard machine learning algorithms, we reduce each variable-length sequence of visits into one “summary” visit using a convex combination. We investigate several reduction approaches, each giving different weights to each visit. We evaluate the predictive performance on two research cohorts with different characteristics to assess the generalization capability of the models.

Secondly, we investigate the association between genetic risk scores and impulse control disorders in Parkinson’s disease. Many phenotypes are known to be heritable, yet less is known about which parts of the genomes and how they contribute to this heritability. A genetic risk score is a single score indicating, given one’s genome, their risk of developing a given phenotype (Wray et al., 2007). For instance, genetic risk scores for schizophrenia and bipolar disorder have been associated with creativity (Power et al., 2015). Recently, the genetic risk score of Parkinson’s disease has been reported not to be associated with ICDs in PD (Ihle et al., 2020). We investigate the association between 40 generic risk scores representing a broad range of phenotypes, and ICDs in PD, in two research cohorts.

Finally, we investigate the integration of static data in recurrent neural networks. We review the literature on this topic and identify four approaches. Besides the dummy approach consisting in removing static data, the most common approach is to have static and dynamic data in their own branches in the network. This approach is not specific to combining static and dynamic data, and is commonly used to integrate multimodal data in artificial neural networks (Hao et al., 2019; Mobadersany et al., 2018). The two other identified approaches consist in treating static data as dynamic data (Leontjeva and Kuzovkin, 2016; Rahman et al., 2020) and initializing the parameters of the recurrent neural unit using the static features (Kristensen and Burelli, 2019). We propose a new approach consisting in modifying the dynamic features using the static features. We investigate the predictive performance of the five approaches in the use case of predicting ICDs in PD, where the static features are socio-demographic and genetic features.
Chapter 1

Background

Parkinson’s disease is the second most frequent neurodegenerative disorder after Alzheimer’s disease (Nussbaum and Ellis, 2003). In France, 150,000 people were affected by PD in 2010 and over 250,000 are expected to be affected in 2030 (Wanneveich et al., 2018). To date, no cure for this disease exists and the quality of life of the patients slowly but steadily decreases until death. Its economic impact is substantial as the cost in the United Kingdom was estimated to be between £449 million and £3.3 billion annually in 2007 (Findley, 2007). The social impact of PD is also important as the quality of life of PD cases is heavily reduced due to the large range of impairing symptoms, increasing caregiver burden.

Besides the three cardinal motor symptoms of PD that are tremor, bradykinesia, and rigidity (Jankovic, 2008), many non-motor symptoms often occur during the course of the disease including cognitive, sleep, dysautonomic, and behavioral disorders (Chaudhuri et al., 2006). There is no cure for PD. The dopamine replacement therapy alleviate motor symptoms, but is hampered by motor complications (fluctuations, dyskinesia) and adverse effects. Impulse control disorders, a class of behavioral psychiatric disorders characterized by impulsivity, is a frequent adverse effect of replacement dopamine therapy (Corvol et al., 2018). Predicting which subjects will develop these disorders and when is challenging, but of great importance because of their familial, social, economic or legal impact.

In this section, we introduce Parkinson’s disease, from pathophysiology to symptoms to medications. Then we define impulse control disorders and detail in which populations they have been studied, and review the literature on impulse control disorders in Parkinson’s disease. Next we introduce the main concepts of machine learning. Finally we discuss how machine learning can be helpful to tackle impulse control disorders in Parkinson’s disease.
1.1 Parkinson’s disease

1.1.1 History

The first clear clinical description of Parkinson’s disease was provided in 1817 by James Parkinson in his *Essay on the Shaking Palsy* (Parkinson, 2002), in which he defined shaking palsy as:

Involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forwards, and to pass from a walking to a running pace: the senses and intellects being uninjured

and used the term *paralysis agitans* to describe individuals with this disorder. In his essay, he reported six cases that he had seen as patients or that he had observed during his wanderings through the streets near his home in Hoxton Square (Lees, 2007).

Jean-Martin Charcot, the father of modern neurology (Gomes and Engelhardt, 2013), deepened the knowledge on this disorder with his studies between 1868 and 1881, notably distinguishing between rigidity, weakness and bradykinesia (Lees, 2007). He also advocated the renaming of the disorder in honor of James Parkinson (Lees, 2007).

Landmarks on the understanding of the disease include the description of microscopic particles, later called Lewy bodies, in the brains of PD cases by Friedrich Lewy in 1912 (Holdorff, 2006), the report that the substantia nigra was the main structure affected in the brain by Konstantin Tretiakoff in 1919 (Goedert et al., 2013), the underlying biochemical changes in the brain by Arvid Carlsson and Oleh Hornykiewicz in the 1950s (Lees, 2007), and the discovery of alpha-synuclein being the main component of Lewy bodies by Spillantini and others in 1997 (Spillantini et al., 1997).

Antiparkinsonian effects of anticholinergics were first described in 1868 by Leopold Ordenstein, a student of Jean-Martin Charcot (Kim et al., 2017). In his thesis, he states that “Monsieur Charcot has begun to prescribe 2 or 3 granules of hyoscyamine daily, approximately 1 mg each. This medication was able to provide several hours of rest for some patients. Apparently, further observations are necessary to make a decision about this medication”. In 1957, Arvid Carlsson showed that levodopa reversed the akinetic effect of reserpine, a drug that lowers blood pressure and slows heart rate, in rabbits (Carlsson et al., 1957). In 1960, Oleh Hornykiewicz published a landmark paper showing for the first time a significant depletion of dopamine in the caudate and putamen of patients only with PD or postencephalitic parkinsonism (Ehringer and Hornykiewicz, 1960). The successful introduction of high dosage levodopa therapy occurred in 1967 (Cotzias et al., 1967). Before, anticholinergics remained the only available medical therapy for Parkinson’s disease. The 1960s were also marked by the first observation of the antiparkinsonian effects of amantadine. In the 1980s, dopamine agonists were tested
as monotherapy in early PD and two catechol-O-methyltransferase (COMT) inhibitors were found to be orally active, following the discovery of monoamine oxidase (MAO) as the mechanism for inactivating the monoamines levodopa decarboxylase enzyme in the 1930s (Kim et al., 2017).

### 1.1.2 Classification

In the tenth revision of the International Statistical Classification of Diseases and Related Health Problems, the code for Parkinson’s disease is G20, belonging to the group of extrapyramidal and movement disorders (G20–G26) among the diseases of the nervous system (G00–G99).

The main motor symptoms of PD, called parkinsonism, consist of bradykinesia and one of two other physical signs: muscular rigidity and tremor at rest (Jankovic, 2008). Parkinson’s disease is the most prevalent form of parkinsonism and is often called idiopathic parkinsonism, that is parkinsonism with no identifiable cause (Samii et al., 2004). Drugs, toxins, infections, and brain lesions such as stroke can lead to parkinsonism. Parkinsonism is not exclusive to PD and can be found in a group of other diseases often called atypical parkinsonism, consisting of other features differentiating them from PD. This group includes multiple system atrophy, progressive supranuclear palsy, Lewy body dementia and corticobasal degeneration (Samii et al., 2004).

### 1.1.3 Pathophysiology

The pathological hallmark of PD is cell death in the basal ganglia, particularly in the ventral component of the substantia nigra pars compacta (Davie, 2008). By the time of death, the substantia nigra pars compacta has lost up to 70% of its neurons in comparison to unaffected individuals. Death of astrocytes and a significant increase in the number of microglia in the substantia nigra also occur (Dickson, 2018).

Figure 1.1 illustrates the primary motor circuits in the basal ganglia. The basal ganglia are functionally connected to other brain regions via the motor, oculo-motor, associative, limbic, and orbitofrontal pathways (Obeso et al., 2008). The motor pathway connects the basal ganglia to the motor cortex, which is involved in the planning, control, and execution of voluntary movements. The oculo-motor pathway links the basal ganglia to the frontal eye fields, which is responsible for saccadic and voluntary eye movements. The cerebral cortex is connected to the basal ganglia via the associative pathway, and enable to support abstract thinking and language, produce a meaningful perceptual experience of the world, and enable us to interact effectively. The limbic pathway connects the basal ganglia to the limbic system, which supports a variety of functions including emotion, behavior, motivation, long-term memory, and olfaction. The orbitofrontal cortex is connected to the basal ganglia via the orbitofrontal pathway, which is involved in the cognitive process of decision-making.
Figure 1.1: Schematic overview of the primary motor circuits in the basal ganglia, the indirect (left) and direct (right) pathways (reproduced from (Harris et al., 2020b)). D1: D1 receptors; D2: D2 receptors; DA: dopamine; ENK: enkephalin; GLU: glutamate; NUC: nucleus; PPN: pedunculopontine nucleus; SP: substance P; SUB: substantia.

Dopamine neurons of the substantia nigra pars compacta mainly innervate the motor pathway, hence the predominance of the motor symptoms. However, the mesolimbic and mesocortical pathways have their somas in the ventral tegmental area, which is relatively sparsely impacted in PD. The motor symptoms are actually assumed to be caused by the impairment of these pathways rather than the motor pathway (Obeso et al., 2008).

1.1.4 Diagnosis

A definite diagnosis of Parkinson’s disease requires autopsy, the final proof being the presence of Lewy bodies in the midbrain (Samii et al., 2004). Nonetheless, clinical diagnosis of this disorder has become more rigorous and several criteria have been proposed (Calne et al., 1992; Hughes et al., 1992; Postuma et al., 2015; Ward and Gibb, 1990). They include confidence levels such as clinically possible, clinically probable and clinically definite, and rely on the presence of parkinsonism, response to antiparkinson drugs and exclusion criteria that would favor another cause for the presence of parkinsonism (Samii et al., 2004).
1.1. Parkinson’s disease

1.1.5 Symptoms

The symptoms of Parkinson’s disease are numerous and have a substantial negative impact on the quality of life of the individuals (Jankovic, 2008). Apart from the recognizable motor symptoms, many other symptoms occur frequently during the course of the disease. Particularly, a wide range of neuropsychiatric disorders have been reported in individuals with PD (Balestrino and Martinez-Martin, 2017).

Motor symptoms

The three cardinal motor symptoms of Parkinson’s disease are bradykinesia, rigidity, and rest tremor (Jankovic, 2008). Other typical symptoms of parkinsonism include postural instability, flexed posture and freezing usually occurring later in the course of the disease and leading to falls (Jankovic, 2008; Kalia and Lang, 2015).

Akinesia, bradykinesia and hypokinesia are the hallmarks of basal ganglia disorders, and includes difficulties with planning, initiating and executing movement, and with performing sequential and simultaneous tasks. Bradykinesia refers to slowness of movement and is the most characteristic clinical feature of PD. Bradykinesia may be associated with hypokinesia (reduction in movement amplitude) or akinesia (poverty of action and difficulty initiating movements) (Moustafa et al., 2016).

The initial manifestation is usually slowness in performing activities of daily living, slow movement and reaction times (slowness of walking), including difficulties with tasks requiring fine motor control such as handwriting (micrographia), using utensils and buttoning. Assessment of bradykinesia usually includes having patients perform rapid, repetitive, alternating movements of the hand and heel taps and observing slowness and decreasing amplitude (Jankovic, 2008).

Rigidity is characterised by increased resistance and is usually accompanied by the “cogwheel” phenomenon, that is a circular jerking rigidity in flexion and extension in a background of tremor. Rigidity can occur at many locations, including neck, shoulders, hips, wrists and ankles. Reinforcing manoeuvres tend to increase rigidity and can be used to detect mild cases of rigidity (Jankovic, 2008).

Tremor at rest is the most recognizable symptom of PD. Tremors are typically unilateral at disease onset, occur in the rest position at a frequency between 4 and 6 Hz, disappear during action, and are usually prominent in the distal part of extremities (Jankovic, 2008). In particular, hand tremors consist of the tendency of the thumb and the index finger to approximate one another while trembling as if an object was being rolled between the two fingers. The term “pill-rolling” is often used to describe these tremors because of the similarity to the technique used by pharmacists to fashion a pill by rolling a substance between the two fingers (Cooper et al., 2008). Rest tremor in patients with PD can also involve the lips, chin, jaw and legs (Jankovic, 2008).

Postural instability due to loss of postural reflexes is usually a symptom of the late
stages of PD and generally occurs after the onset of other clinical features. The pull test is often used to assess postural instability: the patient is quickly pulled backward by the shoulders to assess the degree of retropulsion. Taking more than two steps backwards or the absence of any postural response indicates an abnormal postural response. Postural instability and freezing of gait are the most common causes of falls and contribute substantially to the risk of hip fractures (Jankovic, 2008).

Rigidity and postural deformities can result in flexed posture (camptocormia), such as flexed neck, and usually occur in a late stage of the disease (Jankovic, 2008).

Although the dopamine denervation is always bilateral in PD, it is commonly asymmetric, and the symptoms typically occur unilaterally at the onset of the disease, affecting the other part of the body during disease progression. Akinesia, tremor, and rigidity are responsive to the dopamine replacement therapy which typically improve the symptoms by more than 70% in most patients. By contrast, postural instability and gait disturbance are not poorly responsive to treatment.

Non-motor symptoms

Many non-motor symptoms have also been reported in Parkinson’s disease and can impact the quality of life of the subjects and caregiver burden more than the motor symptoms (Hiseman and Fackrell, 2017). Indeed, these symptoms are not responsive to the treatment and may even worsen with dopamine replacement therapy, and largely contribute to the burden of the disease for the patients and the caregivers. Neuropsychiatric symptoms are particularly common during the course of the disease (Balestrino and Martinez-Martin, 2017).

Major depressive disorder is frequent in PD, with an approximated 17% prevalence. Comorbid depression worsens cognition, function, and quality of life, and increases caregiver burden and mortality. Symptomatic overlap between major depression disorder and PD can make appropriate detection and treatment difficult (Goodarzi et al., 2016).

Up to 55% of PD patients experience substantial anxiety symptoms, and up to 40% have an anxiety disorder as defined by the criteria of the Diagnostic and Statistical Manual of Mental Disorders. The most common anxiety disorders in PD are generalized anxiety disorder, and social and other phobias (Broen et al., 2016).

Most PD patients suffer from cognitive decline or dementia during the course of the disease. The prevalence of mild cognitive impairment is around 25% in individuals with PD but without dementia (Litvan et al., 2011). The point prevalence of PD dementia is approximately 30% and its cumulative prevalence is at least 75% for PD patients surviving more than 10 years (Litvan et al., 2011). Cognitive impairment mostly affect executive and visuo-spatial functions, rather than memory disturbances, and heavily impacts functioning, caregiver burden and mortality (Goldman et al., 2018).

Sleep disturbances are common in PD and consist mainly of nighttime sleep difficulties such as insomnia, restless legs syndrome, rapid eye movement sleep behavior
disorder, and sleep-disordered breathing, but also of excessive daytime sleepiness. The prevalence of insomnia, based on physician interview, is estimated to be around 30–59% (Chahine et al., 2017). Daytime sleepiness can make individuals with PD quit driving, increasing caregiver burden. Sleepiness can be related to the disease itself, but is also an adverse effect of dopamine replacement therapy.

The majority of PD subjects also suffer from gastrointestinal symptoms, constipation being considered the most prominent (Mertsalmi et al., 2017). Other gastrointestinal symptoms include drooling, taste impairment, swallowing disorders (Fasano et al., 2015), and irritable bowel syndrome (Mertsalmi et al., 2017).

Apart from constipation, other autonomic dysfunction occurs frequently, the most common symptoms being orthostatic hypotension, urinary and sexual dysfunction, abnormal sweating and seborrhoea (Jankovic, 2008).

A number of neuro-ophthalmological abnormalities may be seen in patients with PD, including visual hallucinations, ocular surface irritation, decreased blink rate, altered tear film, blepharospasm and decreased convergence (Biousse et al., 2004).

Impulse control and related behaviors are common comorbidities and are strongly associated with dopamine replacement therapy. Almost half of PD patients are expected to develop impulse control disorders five years after PD onset (Corvol et al., 2018). The four major ICDs that have been reported in PD are pathological gambling, compulsive shopping, binge eating and hypersexuality (Weintraub and Claassen, 2017). Other related impulsive-compulsive behaviors include dopamine dysregulation syndrome (Cilia et al., 2014), punding (Evans et al., 2004) and hobbyism (Callesen and Damholdt, 2017).

1.1.6 Medications and their limitations

Contrary to Alzheimer’s disease, for which there exists no treatment that substantially decreases the magnitude of the main symptoms, several therapies are effective at limiting the decrease in quality of life of individuals with PD (Fahn, 2008). The most simple yet efficient therapy is dopamine replacement therapy, which consists in replacing the loss of dopamine due to the cell death in the basal ganglia. Its main classes of medications consist of levodopa, dopamine agonists, and inhibitors. Other therapies include deep brain stimulation (Herrington et al., 2016) and exercise programs (Ahlskog, 2011). Figure 1.2 and Figure 1.3 summarize the treatment options for PD.

Levodopa Levodopa is an abbreviation of L-3,4-dihydroxyphenylalanine and is the precursor to dopamine (Fahn, 2008). Contrary to levodopa, dopamine itself is unable to cross the blood-brain barrier and cannot be used to treat PD (Zahoor et al., 2018). After absorption and transit across the blood-brain barrier, levodopa is converted into the neurotransmitter dopamine by DOPA decarboxylase. Patients are usually administered low dose of levodopa, with the dose being adjusted based on the patient’s response to treatment and balanced against the adverse effects experienced. Although levodopa
Chapter 1. Background

Early PD to prevent/delay disease progression

- **Clinically useful**: None to date
- **Not useful**: Pramipexole; Co Q10, Creatine
- **Investigational**: Selegiline, rasagiline, ropinirole, vitamin D, exercise

Early PD requiring symptomatic therapy

- **Clinically useful**: Non-ergot DA (piribedil, pramipexole IR and ER, ropinirole IR, rotigotine), Ergot DA (cabergoline, pergolide); Levodopa preparations (IR, CR, ER), MAO-B inhibitors (selegiline and rasagiline); anticholinergics
- **Possibly useful**: Non-ergot DA (ropinirole PR), Ergot DA (bromocriptine), amantadine

Early or stable PD requiring adjunct therapy to levodopa

- **Clinically useful**: Non-ergot DA (piribedil, pramipexole IR and ER, ropinirole IR, rotigotine), rasagiline, zonisamide; anticholinergics
- **Possibly useful**: Ergot DA (bromocriptine), amantadine
- **Investigational**: selegiline, early (up to 4 years) bilateral STN DBS
- **Unlikely useful**: Tolcapone
- **Not useful**: Entacapone, safinamide

Figure 1.2: Evidence-based medicine review of treatment options for motor symptoms of early PD (reproduced from (Fox et al., 2018)).

### Treating motor fluctuations

- **Clinically useful**: Non-ergot DA (pramipexole, ropinirole, rotigotine, apomorphine intermittent injections, pergolide); levodopa ER; COMT inhibitors (entacapone; opicapone); MAO-B inhibitors (rasagiline, safinamide, zonisamide); LCIG; bilateral DBS (STN or GPi)
- **Possibly useful**: Ergot DA (bromocriptine, cabergoline); istradefylline; tolcapone; Non-ergot DA (apomorphine infusion)
- **Investigational**: Selegiline, rasagiline, ropinirole, vitamin D, exercise

### Treating dyskinesia

- **Clinically useful**: Amantadine; clozapine; LCIG, bilateral DBS surgery (STN or GPi); unilateral pallidotomy

### Treating specific/general motor symptoms

- **Clinically useful**: Physiotherapy
- **Possibly useful**: Rivastigimine (gait and balance); Exercise-based movement strategy training (gait and balance); formalized patterned exercises (gait and balance); speech therapy (speech and swallowing); occupational therapy; thalamic surgery (DBS or thalamotomy) (tremor)
- **Investigational**: Donepezil (gait and balance); methylphenidate (gait and balance); memantine (gait and balance); cannabidiol; technology-based movement strategies; acupuncture; rTMS; tDCS

Figure 1.3: Evidence-based medicine review of treatment options for motor symptoms of treated PD optimized on levodopa (reproduced from (Fox et al., 2018)).

is effective against the main motor symptoms, it comes up with side effects such as dyskinesia (involuntary movements) and fluctuations in effectiveness (National Clinical Guideline for Diagnosis and Management in Primary and Secondary Care, 2006). Levodopa is also ineffective against several motor (gait, speech) and non-motor (cognitive, sensory, vegetative) PD symptoms (You et al., 2018).

**Dopamine agonists** An agonist is a chemical that binds to a receptor and activates the receptor to produce a biological response. Dopamine agonists stimulate the activity of the dopamine system by binding to the dopaminergic receptors and, unlike levodopa, do not need to be converted into dopamine (Zahoor et al., 2018). Initial treatment with dopamine agonists allows for a delay in the use of levodopa, which may curtail the impact of the problematic motor complications (Rascol et al., 2000). However dopamine agonists are less potent than levodopa, and are less tolerated than levodopa with higher rate of nausea and vomiting, insomnia, sleepiness, and hallucinations, particularly in the elderly. Ergot DAs have also been progressively abandoned because of their association with heart valve fibrosis (Corvol et al., 2007; Van Camp et al., 2004). One of the most troublesome characteristic side effects of dopamine agonists is probably impulse control disorders and related behaviors, including pathological gambling, hypersexuality, binge eating, compulsive shopping, punding, and hobbyism.

**Inhibitors of levodopa metabolism** An inhibitor is a substance that decreases the rate of, or prevents, a chemical reaction. Inhibiting enzymes that are involved in dopamine degradation is the main feature of this class of medications. Monoamine Oxidase B (MAO-B) is one of the main enzymes involved in the breakdown of dopamine, thus reducing the activity of this enzyme results in increased dopaminergic activity within the striatum (Zahoor et al., 2018). The intake of MAO-B inhibitors relieves motor symptoms in PD patients, and as with dopamine agonists they may be used as an initial treatment option. The main side effects of MAO-B inhibitors are increased dyskinesia and headaches (Connolly and Lang, 2014). Catechol-O-methyl transferase is another enzyme involved in dopamine as well as in levodopa degradation. COMT inhibitors are used as adjunctive therapy to levodopa by prolonging its duration of action (Zahoor et al., 2018). The most common adverse effects of both entacapone and tolcapone, the most-used COMT inhibitors, are increased dyskinesia and diarrhoea in up to 20% of the treated patients (You et al., 2018).

**Others** Levodopa, dopamine agonists and inhibitors are all designed to increase dopaminergic activity in the striatum. A few drugs that act through non-dopaminergic mechanisms are also used in the treatment of PD (Zahoor et al., 2018). Anticholinergics, by acting as antagonists at cholinergic receptors, limit the activity of the neurotransmitter acetylcholine. Their most common adverse effects include hallucinations, blurred
vision, dry mouth, constipation, drowsiness, memory problems, and increased dyskinesia (Zahoor et al., 2018). Amantadine, which was initially developed as an antiviral drug for treating flu, has subsequently been used for the treatment of PD. It may be used to treat rigidity, rest tremor, and is also used to treat levodopa-induced dyskinesia (Ory-Magne et al., 2014; Zahoor et al., 2018). While generally well tolerated, possible adverse effects associated with the use of amantadine include hallucinations, confusion, blurred vision, impaired concentration, nausea and vomiting (Zahoor et al., 2018).

1.1.7 Motor complications

Despite its spectacular effects on the core motor symptoms of Parkinson’s disease, levodopa is not a perfect drug as it does not fulfil all the needs of PD patients. The long-term outlook for PD patients is hampered by the occurrence of motor complications: motor fluctuations and dyskinesia. Levodopa and inhibitors of levodopa metabolism are notably associated with increased dyskinesia (You et al., 2018). Dyskinesia and motor fluctuations affect virtually all patients but the delay in their occurrence is highly variable. More than 90% of PD patients are expected to experience motor complications after 10 years (Hely et al., 1999; Mazzella et al., 2005).

**Motor fluctuations** Motor fluctuations are characterised by wearing-off, that is worsening or reappearance of motor symptoms before the next levodopa dose resulting in an “off” state that improves when the next dose is taken (“on” state) (You et al., 2018). There are two kinds of response to levodopa: the short duration response (SDR) and the long-duration response (LDR). The former corresponds to the motor improvement following a single dose of levodopa and lasts from minutes to hours (Muenter and Tyce, 1971). Its effect is immediately lost if levodopa is stopped. The latter has a slower development and builds up during repeated levodopa dosing, taking days to weeks to come into effect, but also decays gradually over a similar span of time after levodopa has been withdrawn (Anderson and Nutt, 2011). Both mechanisms are present from the beginning of PD treatment. The SDR accounts for a half to two thirds of the motor response, while the LDR accounts for the remaining part (Ogasahara et al., 1984). However, their effects are not strictly additive but overlapping and even show a different time course as the disease progresses. In the early stages of PD, the LDR predominates and masks most of the SDR, thus patients have a stable response to levodopa (Nutt and Holford, 1996). With disease progression and long-term levodopa treatment, the LDR decreases and the SDR shortens, with a more immediate onset and decline and a greater difference between baseline and peak response. Therefore, the masking of the SDR by the LDR dwindles and patients experience motor fluctuations (Nutt and Holford, 1996).
Levodopa-induced dyskinesia  Dyskinesias are abnormal movements of the limbs, the trunk and the face induced by the dose of levodopa. Many patients do not recognize levodopa-induced dyskinesias and do not experience any disability from the movements. As is, treating every dyskinesia is not necessarily essential, and clinicians focus on preventing worsening or reducing only disabling, bothersome dyskinesia with medical or surgical strategies (Aquino and Fox, 2015). Dyskinesia is most common at the peak-level of levodopa action, and consists of chorea, dystonia, and ballism, and to a lesser extent myoclonus (Nutt, 1990). Choreic movements in the limbs are the most common form of peak-dose dyskinesia, but dystonic posturing in the limbs can also occur. These involuntary movements may be initially mild and mainly involve the neck, and less commonly affect lips and jaw. They later spread to involve the trunk and can become more bothersome movements (Aquino and Fox, 2015). Myoclonus is a brief, involuntary, irregular twitching of a muscle or a group of muscles. Levodopa-induced myoclonus has been described as either spontaneous, action induced, or stimulus sensitive, and occurs within 10 to 20 minutes of levodopa administration (Aquino and Fox, 2015). Dyskinesia also occurs at low dose of levodopa action. Dyskinesia occurring during off-period is predominantly dystonic and mostly affects the legs and feet (Luquin et al., 1992). Off-period dystonia may completely disappear after withdrawal of levodopa for a few days or weeks (Aquino and Fox, 2015). When the levels of levodopa are rising and falling, at the beginning or end-of-dose respectively, dyskinesia can also occur and is known as “diphasic dyskinesia”. Diphasic dyskinesias are less common, tend to mainly affect the legs, and can involve slow stereotypical alternating leg movements (Luquin et al., 1992).

1.2  Impulse control disorders

Impulse control disorders include conditions involving problems in the self-control of emotions and behaviors such as pyromania or kleptomania (American Psychiatric Association, 2013). The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association, 2013) has a specific chapter on disruptive, impulse-control and and conduct disorders. Impulse control disorders have been studied among college students (Leppink et al., 2016b; Odlaug and Grant, 2010) and elderly patients (Tamam et al., 2014), as well as in several other disorders.

1.2.1  Definition of specific impulse control disorders

Intermittent explosive disorder  The main feature of intermittent explosive disorder is recurrent behavioral outbursts representing a failure to control aggressive impulses. They are manifested by either verbal or physical aggression, or destruction or belongings. The magnitude of aggressiveness during these outbursts highly exceeds the provocation or any anticipated psychosocial stressors. The recurrent outbursts
1.2. Impulse control disorders

are not purposeless, unpremeditated, and cause either impairment in occupational or interpersonal functioning, or marked distress in the individual (American Psychiatric Association, 2013).

Kleptomania Kleptomania is characterized by recurrent failures to resist impulse to steal objects that are not needed for their monetary value or for personal use. Individuals with kleptomania feel an increasing sense of tension shortly before committing the theft, then pleasure, relief or gratification at the time of commitment. Stealing is not committed in response to a hallucination or a delusion, or to express vengeance or anger. (American Psychiatric Association, 2013)

Pyromania Pyromania is characterized by the multiple episodes of deliberate and purposeful fire setting. Persons with pyromania experience affective or tension arousal before setting a fire. They are interested in fire in situational contexts and are often regular watchers at fires. The fire setting is not done for profit and does not result from impaired judgement (American Psychiatric Association, 2013).

Pathological gambling The main feature of pathological gambling is recurrent and persistent dysfunctional patterns of gambling behavior leading to clinically significant distress or impairment. Pathological gamblers may need to gamble increasing amounts of money in a bid to achieve the desired excitement, may be irritable or restless when trying to cut down or stop gambling, often gamble when feeling distressed or lie to conceal the amount of involvement with gambling. The gambling behavior is not better explained by a manic episode. (American Psychiatric Association, 2013).

Compulsive sexual behavior Compulsive sexual behavior, also called hypersexuality, is characterized by persistently or recurrently present sexual or erotic thoughts or fantasies and desire for sexual activity (American Psychiatric Association, 2013). Individuals with this disorder feel driven or compelled to perform the behavior, which may cause distress (Dell’Osso et al., 2006). Impulsive-compulsive sexual disorder include unconventional sexual behaviors with a disturbance in the object of sexual gratification or in the expression of sexual gratification, and conventional sexual behaviors that have become excessive or uncontrolled (Dell’Osso et al., 2006).

Internet addiction disorder Internet addiction disorder is defined as a persistent and recurrent use of the Internet (American Psychiatric Association, 2013). Major symptoms of this disorder include preoccupation with the Internet, unsuccessful repeated efforts to decrease Internet use, staying online longer than intended, jeopardizing significant relationship, job, educational or career opportunity because of the Internet,
lying to relatives or physicians about the involvement with the Internet, and using the Internet a way of escaping from problems or of regulating mood (Young, 1998).

**Compulsive buying disorder**  Compulsive buying disorder is characterized by excessive shopping cognitions and buying behavior that leads to distress or impairment (Black, 2007). Individuals with compulsive buying disorder are preoccupied with shopping and spending, and devote significant time to these behaviors. Shopping and spending are highly associated as window shopping is an uncommon pattern. Compulsive buying behaviors can be split into four phases: anticipation, preparation, shopping, and spending (Black, 2007). In the first phase, individuals develop preoccupations and thoughts with either shopping or having a specific item. The second phase consists in preparing for shopping and spending, such as deciding where to go. The third phase involving shopping and spending itself, which often procures high excitement and even sexual feelings (Schlosser et al., 1994). The fourth phase consists of the moment after the purchase, which is often experienced as a disappointment or a letdown. Common purchased items during these behaviors include clothing, shoes, and household items (Christenson et al., 1994; Miltenberger et al., 2003; Schlosser et al., 1994).

**Binge eating disorder**  The main feature of binge eating disorder is recurrent episodes of binge eating. An episode of binge eating is characterized by eating, in a discrete span of time, a much larger amount of food than most people would eat under similar circumstances and in a similar period of time, and a sense of lack of control over eating during this span of time. These episodes are often associated with eating much more quickly than normal, eating until feeling uncomfortably full, eating large food quantities when not feeling physically hungry, eating alone because of embarrassment, and feeling disgusted with oneself, depressed, or very guilty afterward. (American Psychiatric Association, 2013)

**Excoriation disorder**  Excoriation disorder, also called skin picking disorder, is characterized by recurrent skin picking resulting in skin lesions (American Psychiatric Association, 2013). Individuals with excoriation disorder experienced repeated attempts to curtail or stop skin picking. The skin picking causes significant distress or impairment in important areas of functioning and cannot be attributed to the physiological effects of any medical condition. Although it is now classified as an obsessive-compulsive disorder (American Psychiatric Association, 2013), excoriation disorder used to be classified in the impulse disorder category in the tenth revision of the International Statistical Classification of Diseases and Related Health Problems (Black and Grant, 2014).
1.2.2 Studies on impulse control disorders in subpopulations

Impulse control disorders have been studied in subpopulations, defined by an age range or another disorder.

Besides Parkinson’s disease, which we will detail in the next section, the most studied disorders are obsessive-compulsive disorders (Fontenelle et al., 2005; Grant et al., 2006). ICDs and obsessive-compulsive disorders overlap in their phenomenology, co-morbidity, pathophysiology and family history (Fontenelle et al., 2011). Compulsive and impulsive disorders have been viewed at the opposite ends of a single dimension: the former motivated by a desire to avoid harm and the latter by reward-seeking behavior (Fineberg et al., 2010). The prevalence of ICDs in patients with obsessive-compulsive disorders is estimated to be around 11–35%, skin picking being the most common comorbid ICD (Fontenelle et al., 2005; Grant et al., 2006, 2010).

A review on ICDs and bipolar disorder highlighted the high number of common features for both disorders: phenomenological similarities, including pleasurable, dangerous, or harmful behaviors, impulsivity, and similar affective symptoms and dysregulation; onset in late childhood or early adulthood with episodic and/or chronic course; high comorbidity with one another and comparable comorbidity with other psychiatric disorders; high familial rates of mood disorder; and response to mood stabilizers and antidepressants (McElroy et al., 1996).

Impulse control disorders have been reported in Tourette syndrome (Jankovic and Kurlan, 2011), restless leg syndrome (Cornelius et al., 2010) and Perry syndrome (Mishima et al., 2015).

Impulse control disorders have also been studied in university students. In this subpopulation, the prevalence is estimated to be around 10% (Odlaug and Grant, 2010) and are associated with stress (Leppink et al., 2016b) and depression (Leppink et al., 2016a). Among elderly people, the prevalence is estimated to be around 17% and ICDs are associated with childhood conduct disorder and alcohol/substance abuse (Odlaug and Grant, 2010).

1.3 Impulse control disorders in Parkinson’s disease

Since the first reports of impulse control disorders in Parkinson’s disease in the early 2000s, impulse control disorders have been increasingly recognized. Given their potential impact on life functioning, including activities of daily living, interpersonal relationships, and social-occupational functioning, clinicians growingly pay specific attention to these impulsive behaviors (Weintraub and Claassen, 2017). ICDs are actually not symptoms of Parkinson’s disease itself, but adverse effects of dopamine replacement therapy (de la Riva et al., 2014). ICDs have been broadly studied in PD, from prevalence to assessment to comorbidities.
1.3.1 Epidemiology

One of the earliest case reports dates back to 2003, which identified nine patients (0.5% of the sample) with pathological gambling (Driver-Dunckley et al., 2003). In 2010, the DOMINION study aimed at evaluating the point prevalence estimates of the four main ICDs among 3090 medicated PD patients in the United States and Canada (Weintraub et al., 2010a). One or more ICDs were identified in 13.6% of patients (compulsive buying in 5.7%, gambling in 5.0%, binge-eating disorder in 4.3%, and compulsive sexual behavior in 3.5%), with 3.9% of participants having two or more ICDs. A more recent longitudinal analysis of ICDs in a French research cohort estimated the 5-year cumulative incidence to be about 46% (Corvol et al., 2018).

As for any psychiatric disorder, environmental factors may influence the presence of ICDs in PD. In particular, cultural factors seem to impact the prevalence of specific ICDs. Studies in Turkey and India reported very low prevalences for pathological gambling (Kenangil et al., 2010; Sarathchandran et al., 2013), while this ICD has one of the highest prevalence in most Western studies (Baig et al., 2019; Garcia-Ruiz et al., 2014; Hurt et al., 2014; Weintraub et al., 2010a). Gambling is illegal in Turkey and heavily restricted in India, whereas it is legal in Western countries, and an important part of the American culture. Various studies lack uniformity to assess ICDs, and the definition itself of ICDs is subject to cultural differences (Weintraub and Claassen, 2017).

1.3.2 Assessment and diagnosis

As impulse control disorders have been increasingly recognized in Parkinson’s disease, several screening tools and rating scales have been developed and used to assess and diagnose them.

The Movement Disorder Society-Sponsored Revision of the Unified Parkinson’s Disease Rating Scale (MDS-UPDRS) has an item entitled Features of dopamine dysregulation syndrome in the part assessing non-motor aspects of experiences of daily living (Goetz et al., 2008). This single item encompasses impulse control disorders, dopamine dysregulation syndrome, punding, and hobbyism.

The Questionnaire for Impulsive-Compulsive Disorders in Parkinson’s Disease (QUIP) was developed as a screening instrument for ICDs and related behaviors and is structured to be consistent with diagnostic criteria or defining clinical characteristics as described in the Diagnostic and Statistical Manual of Mental Disorders (Weintraub et al., 2009). Its three sections focus on (i) the four most common ICDs, (ii) punding and hobbyism, and (iii) compulsive medication use.

The Rating Scale version of the QUIP (QUIP-RS) was derived from the QUIP to measure the severity of ICDs (Weintroub et al., 2012). Each item is rated on a 5-point Likert scale and assesses the frequency of the symptoms with a range of scores from 0 (never) to 4 (very often). The sections are similar than the ones in the QUIP, although a
1.3. Impulse control disorders in Parkinson’s disease

A slight difference is that punding and hobbyism have been grouped together (Evans et al., 2019). This scale has been validated in several countries (Choi et al., 2020; Marques et al., 2019; Probst et al., 2014).

The Ardouin Scale of Behavior in Parkinson’s Disease consists of eighteen items addressing non-motor symptoms, grouped in four parts: general psychological evaluation, apathy, non-motor fluctuations and hyperdopaminergic behaviors (Ardouin et al., 2009).

The Scale for Outcomes in Parkinson’s Disease – Psychiatric Complications is a screening and severity scale that consists of a 7-item questionnaire (Visser et al., 2007). Two items are related to impulsive control disorders: one item for compulsive shopping and pathological gambling, and another one for hypersexuality. Each item score range from 0 (no symptoms) to 3 (severe symptoms) (Evans et al., 2019).

The Minnesota Impulsive Disorders Interview was originally developed in 2008 for the diagnosis of compulsive buying, trichotillomania, kleptomania, pyromania, intermittent explosive disorder, pathological gambling, and compulsive sexual behavior (Chamberlain and Grant, 2018; Grant, 2008). The original version was revised to match the changes made in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (Chamberlain and Grant, 2018).

1.3.3 Associations

A wide range of factors have been associated with impulse control disorders in Parkinson’s disease, from personality traits to psychiatric comorbidities to medications.

Demographics Significant differences between sexes have been observed, with men developing more pathological gambling and hypersexuality disorders and women developing more compulsive buying and eating disorders (Weintraub and Claassen, 2017). A younger age has been associated with ICDs in PD in numerous studies (Callesen et al., 2014; Poletti et al., 2013; Pontieri et al., 2015; Weintraub et al., 2010a). The DOMINION study, with 3090 PD patients from the United States and Canada, reported that PD patients with ICDs were most likely unmarried and living in the United States (Weintraub et al., 2010a).

Personality traits Unsurprisingly, the most assessed personality trait was impulsivity, with studies reporting higher impulsivity scores (Sáez-Francàs et al., 2016; Voon et al., 2011) and greater choice impulsivity (Sáez-Francàs et al., 2016). PD patients with ICDs were described as individuals with a higher level of neuroticism and lower levels of agreeableness and conscientiousness (Callesen et al., 2014), particularly among PD patients with pathological gambling (Gescheidt et al., 2016) or hypersexuality (Sachdeva et al., 2014). These patients were also reported to have ineffective coping skills (Olley et al., 2015).
Addictive disorders  A family history of pathological gambling was significantly more prevalent among PD patients with ICDs than those without (Weintraub et al., 2010a). Past and current cigarette smoking has been associated with ICDs (Valença et al., 2013; Weintraub et al., 2010a), so was substance use of caffeine (Bastiaens et al., 2013; Gescheidt et al., 2016), tea, and alcohol (Ramírez Gómez et al., 2017).

Psychiatric comorbidities  Mental illness was reported to be associated with the presence of ICDs, in particular anxiety and depression (Grall-Bronnec et al., 2018; Olley et al., 2015). Higher score of depression (Callesen et al., 2014; Joutsa et al., 2012; Vela et al., 2016; Voon et al., 2011), symptoms of depression (Gescheidt et al., 2016; Pontone et al., 2006), and a history of depression (Auyeung et al., 2011) have been found to be correlated with ICDs. Higher score of anxiety (Leroy et al., 2012; Pontieri et al., 2015; Sachdeva et al., 2014; Voon et al., 2011), trait anxiety (Sáez-Francàs et al., 2016), and a history of anxiety (Auyeung et al., 2011) were also found to be associated with ICDs. Only one study reported a higher obsessive-compulsive score (Voon et al., 2011), although both disorders share several features.

Sleep disturbances  PD patients with ICDs have been reported to have an increased prevalence of sleep disturbances, including daytime sleepiness, worse sleep efficiency, and restless leg syndrome symptoms (Marques et al., 2018; O’Sullivan et al., 2011; Pontieri et al., 2015; Scullin et al., 2013). A strong association was shown between ICD symptoms, specially pathological gambling, and rapid eye movement sleep behavior disorder (Fantini et al., 2015, 2018, 2019, 2020; Ramírez Gómez et al., 2017).

Disease-related factors  Several disease-related factors have been associated with ICDs. Younger age of PD onset (Callesen et al., 2014; Lee et al., 2010; Pontieri et al., 2015; Ye et al., 2011) and longer disease duration (Callesen et al., 2014; Lee et al., 2010; Pontieri et al., 2015) have been found correlated with ICDs. Association between ICDs and higher motor impairment has also been reported (Bastiaens et al., 2013; Callesen et al., 2014; Leroy et al., 2012). A negative association between motor fluctuations or dyskinesias and ICDs has been reported in one study (Ramírez Gómez et al., 2017). In particular, a higher score on the MDS-UPDRS Part I was found in two studies (Rodríguez-Violante et al., 2014; Sáez-Francàs et al., 2016), but it must be noted that one of the item of the MDS-UPDRS Part I is about dopamine dysregulation syndrome.

Medications  Dopamine replacement therapy, specially dopamine agonists, has been strongly associated with ICDs. Ever use, longer cumulative duration, and higher cumulative dose of DAs have been correlated with ICDs (Corvol et al., 2018). The six dopamine agonists that have been approved by the US Food and Drug Administration (pramipexole, ropinirole, cabergoline, bromocriptine, rotigotine, and apomorphine) have
all been associated with ICDs (Grall-Bronnec et al., 2018). Dopamine agonists with a
preferential affinity for D2-like receptors (D2 and D3 receptors), that is pramipexole and
ropinirole, have been reported to have the strongest associations (Moore et al., 2014).
To a lesser extent, associations with levodopa (Pontieri et al., 2015; Weintraub et al.,
2010a) and amantadine (Weintraub et al., 2010b) have also been reported.

**Genetic factors** Association between ICDs and several single-nucleotide polymor-
phisms (SNPs) have been suggested in the following genes: \( \text{DRD3} \) (Castro-Martínez
et al., 2018; Krishnamoorthy et al., 2016; Lee et al., 2009), \( \text{GRIN2B} \) (Lee et al.,
2009; Zainal Abidin et al., 2015), \( \text{HTR2A} \) (Kraemmer et al., 2016; Lee et al., 2012), \( \text{ANKK1} \)
(Hoenicka et al., 2015), \( \text{DRD1} \) (Erga et al., 2018; Zainal Abidin et al., 2015), \( \text{DRD2} \)
(Kraemmer et al., 2016; Zainal Abidin et al., 2015), \( \text{OPRM1} \) (Cormier-Dequaire et al.,
2018), \( \text{DAT1} \) (Cormier-Dequaire et al., 2018), \( \text{LRRK2} \) (Simuni et al., 2020), \( \text{GBA} \)
(Simuni et al., 2020), \( \text{OPRK1} \) (Cormier-Dequaire et al., 2018; Kraemmer et al., 2016), and
\( \text{SLC22A1} \) (Redenek et al., 2019). However a few studies did not report associations
between ICDs and several SNPs from the following genes: \( \text{DRD2} \) (Cormier-Dequaire
et al., 2018; Vallelunga et al., 2012), \( \text{COMT} \) (Vallelunga et al., 2012), \( \text{DAT1} \) (Vallelunga
et al., 2012), \( \text{GRIN2B} \) (Cormier-Dequaire et al., 2018), and \( \text{HTR2A} \) (Cormier-Dequaire
et al., 2018). The Parkinson’s disease polygenic risk score has been reported not to be
associated with ICDs (Ihle et al., 2020).

### 1.3.4 Prediction

While the literature on correlates with ICDs is large, studies focusing on the prediction
of ICDs are very scarce: only three studies with a prediction task have been identified
(Erga et al., 2018; Jesús et al., 2020; Kraemmer et al., 2016).

Kraemmer and others (Kraemmer et al., 2016) developed a clinical-genetic model to
predict incident impulse control disorders in PD. The clinical features consisted of age,
sex, PD treatment and duration of follow-up. The genetic variables consisted of thirteen
candidate variants selected from the following genes: \( \text{DRD2-3} \), \( \text{DAT1} \), \( \text{COMT} \), \( \text{DDC} \),
\( \text{GRIN2B} \), \( \text{ADRA2C} \), \( \text{SERT} \), \( \text{TPH2} \), \( \text{HTR2A} \), \( \text{OPRK1} \), and \( \text{OPRM1} \). They worked on
the Parkinson’s Progression Markers Initiative (PPMI) database, which is an ongoing
longitudinal multi-centre international study designed to identify biomarkers of PD
progression in de novo and drug-naïve (at baseline) patients with PD. The algorithm
trained with the aforementioned variables was a logistic regression.

Erga and others (Erga et al., 2018) also developed a clinical-genetic model, with
slight differences compared to the previous study. The clinical features consisted only
of age and PD treatment. The genetic variables consisted of fifty-six candidate variants
selected from the following genes: \( \text{ADRA2C} \), \( \text{DRD1-5} \), \( \text{SLC6A3} \), \( \text{DDC} \), \( \text{COMT} \), \( \text{SLC6A4} \),
\( \text{TPH2} \), \( \text{HTR2A} \), \( \text{OPRM1} \), \( \text{OPRK1} \), \( \text{GRIN2B} \), and \( \text{BDNF} \). The research cohort used
was the Norwegian ParkWest study, which is a population-based longitudinal study of
incident PD. The trained algorithm was a logistic regression with an elastic-net penalty (Zou and Hastie, 2005).

Jesús and others (Jesús et al., 2020) also developed a clinical-genetic model. The clinical features consisted of sex, age, age at PD onset, years of disease evolution, DA equivalent daily dose, and levodopa equivalent daily dose. The genetic variables consisted of twenty genetic variants selected from the following genes: DDC, DRD1, DRD2, DRD3, COMT, HTR2A, GRIN2B, TPH2, OPRM1, OPRK1, ADRA2C, and BDNF. They worked on a research cohort from the Movement Disorder Clinic of the University Hospital Virgen del Rocío in Seville, Spain. They also trained logistic regression models with the aforementioned variables.

1.3.5 Other behavioral addictions

Although they are not impulse control disorders, several other related behaviors have been reported in Parkinson’s disease and can have a substantial negative impact on the quality of life of the patients. They are often referred to as other behavioral addictions or related behaviors in the literature and consist of dopamine dysregulation syndrome, punding and hobbyism (Weintraub and Claassen, 2017).

Dopamine dysregulation syndrome is characterized by the intake of large doses of dopaminergic drugs in excess of that required to control motor symptoms, endless requests to physicians for larger doses of dopamine replacement therapy or self-escalation of these medications without medical approval despite severe social destructive behaviors (Cilia et al., 2014). The prevalence is estimated to be around 34% in an advanced stage of PD (Cilia et al., 2014). A few cases have been reported in restless leg syndrome (Leu-Semenescu et al., 2009; Salas et al., 2009). A recent systematic review identified only nine case reports of dopamine dysregulation syndrome in non-Parkinson’s disease (Cartoon and Ramalingam, 2019).

Punding was first used to describe the behavior of people addicted to amphetamine (Rylander, 1972; Schiørring, 1981). Punding is a complex stereotyped behavior characterized by an intense fascination with repetitive manipulations of technical equipment, hoarding, grooming, continual handling, examining, and sorting common objects, pointless driving or walkabouts, and the engagement in extended monologues devoid of content (Evans et al., 2004). Punding behaviors often arise from particular habits or pastimes: people who regularly tinkered with technical objects are more likely to develop this kind of punding. Punding is also influenced by subject’s previous occupation: office workers and clerks may shuffle papers or fiddle purposelessly with computers while a seamstress may collect and arrange buttons (Spencer et al., 2011). A study reported the case of a 23-year-old Parkinsonian woman who developed unusual behaviors such as ceaseless sewing, disassembly and reassembly of phones, and coloring of drawings (El Otmani et al., 2015).
Hobbysim is defined as an excessive interest in one or several hobbies such as physical activity, artistic endeavor, do-it-yourself or gardening. For instance, a study reported a 77-year-old Parkinsonian man who started to show excessive hobbyism of painting four years after disease onset (Matsuda et al., 2018).

### 1.4 Machine learning

Machine learning is the process of automatically learning from data. Examples of tasks that machine learning can address include (Hastie et al., 2009):

- Predict the 10-year risk of future coronary heart disease.
- Estimate the amount of glucose in the blood of a diabetic person given the infrared absorption spectrum of that person’s blood.
- Recognize the numbers in a handwritten ZIP code from a digitized image.
- Identify the risk factors for prostate cancer based on clinical and demographic variables.

In most scenarios, one has a target (outcome) measurement that one wants to predict from a set of features. The outcome can be quantitative (amount of glucose) or qualitative (presence or absence of a specific disease). Quantitative outcomes correspond to regression tasks, while qualitative outcomes correspond to classification tasks. One has a training set to train an algorithm and a test set (replication set) to evaluate its performance. These scenarios are supervised learning problems, because the learning process is supervised by the target.

The next sections introduce the notations used for the data and some of the most common machine learning algorithms.

#### 1.4.1 Notations

Let $n$ be the number of samples and $m$ be the number of features. We consider data sets consisting of a $n \times m$ matrix $X$ representing the input data and a $n$ vector representing the target data:

\[
X = \begin{bmatrix}
    x_{11} & \cdots & x_{1m} \\
    \vdots & \ddots & \vdots \\
    x_{n1} & \cdots & x_{nm}
\end{bmatrix}, \quad y = \begin{bmatrix}
    y_1 \\
    \vdots \\
    y_n
\end{bmatrix}
\]
When longitudinal data is available, that is data at several time points, a time index is added:

\[
X^{(t)} = \begin{bmatrix}
    x^{(t)}_1 & \cdots & x^{(t)}_m \\
    \vdots & \ddots & \vdots \\
    x^{(t)}_n & \cdots & x^{(t)}_{nm}
\end{bmatrix}, \quad y^{(t)} = \begin{bmatrix}
y^{(t)}_1 \\
\vdots \\
y^{(t)}_n
\end{bmatrix}
\]

and the input matrices and target vectors are available at several time points:

\[
\left( X^{(1)}, \ldots, X^{(t)}, \ldots, X^{(T)} \right), \quad \left( y^{(1)}, \ldots, y^{(t)}, \ldots, y^{(T)} \right)
\]

When only one sample is considered, the sample index is omitted. Likewise, when only one time point, the time index is omitted. The input data is thus the vector \( \mathbf{x} \) and the target data is \( \mathbf{y} \).

In the case of regression, \( \mathbf{y} \) is a real number. In the case of classification, \( \mathbf{y} \) is a single label. In particular, for binary classification, we consider that both classes are denoted \(+1\) and \(-1\), that is \( \mathbf{y} \in \{-1, +1\} \).

The objective is to predict \( \mathbf{y} \) given \( \mathbf{x} \). The prediction is denoted \( \hat{\mathbf{y}} \). The most general formulation is:

\[
\hat{\mathbf{y}} = g(f(\mathbf{x}))
\]

where \( f \) is the decision function and \( g \) is the final prediction. For regression tasks, \( g \) is the identity function, and the decision function is the final prediction.

1.4.2 Algorithms

Linear models

A linear model is a model that linearly combines the features:

\[
f(\mathbf{x}) = \mathbf{x}^\top \beta = \beta_0 + \sum_{j=1}^{m} \beta_j x_j
\]

The vector \( \beta \) consists of:

- the intercept (constant) \( \beta_0 \), and
- the coefficients \( (\beta_1, \ldots, \beta_m) \), where each coefficient \( \beta_j \) is associated to the feature \( x_j \).

The vector \( \beta \) defines an hyperplane and \( f(\mathbf{x}) \) corresponds to the distance of \( \mathbf{x} \) to this hyperplane. A hyperplane is a subspace whose dimension is one less than that of the original space. For instance, in the two-dimensional case, a hyperplane is a line. In the three-dimensional case, a hyperplane is a plane.
Figure 1.4: Ordinary least squares linear regression. When the input data consists of a single feature, the input and target variables can be visualized on a 2D plot. The ordinary least squares linear regression finds the best linear relationship (line) between both variables.

**Ordinary Least Squares Linear Regression**

The ordinary least squares linear regression is a linear regression model that is trained by minimizing the residual sum of squares between the observed targets in the data set, and the targets predicted by the linear approximation (Hastie et al., 2009):

\[
\hat{y} = f(x) = x^\top \beta = \beta_0 + \sum_{j=1}^{m} \beta_j x_j
\]

\[
\min_{\beta} \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 = \min_{\beta} \sum_{i=1}^{n} \left( y_i - x_i^\top \beta \right)^2 = \min_{\beta} \| y - X \beta \|_2^2
\]

Figure 1.4 illustrates the main concept of the algorithm. When the input data consists of a single feature, the input and target variables can be visualized on a 2D plot. The ordinary least squares linear regression finds the best linear relationship between both variables. In this particular case, a linear relationship is simply a line.

**Logistic Regression**

For binary classification tasks, an hyperplane splits a space into two subspaces. In one subspace, the signed distance to the hyperplane is positive; in the other subspace, the signed distance to the hyperplane is negative. The decision of the algorithm depends on the sign of the signed distance:

\[
\hat{y} = g(f(x)) = \begin{cases} 
+1 & \text{if } f(x) > 0 \\
-1 & \text{if } f(x) < 0 
\end{cases}
\]
Figure 1.5: Decision function of a logistic regression model. A logistic regression is a linear model, that is its decision function is linear. In the two-dimensional case, it separates a plane with a line.

The logistic regression model transforms the signed distance to the hyperplane into a probability using the sigmoid function (Hastie et al., 2009):

\[ f(x) = \beta_0 + \sum_{i=1}^{m} \beta_j x_j \]

\[ \mathbb{P}(y = +1|x) = \sigma(f(x)) = \frac{1}{1 + \exp(-f(x))} \]

By applying the inverse of the sigmoid function, which is known as the logit function, one can see that the natural logarithm of the *odds ratio* is modeled as a linear combination of the features:

\[ \log \left( \frac{\mathbb{P}(y = +1|x)}{\mathbb{P}(y = -1|x)} \right) = \log \left( \frac{\mathbb{P}(y = +1|x)}{1 - \mathbb{P}(y = +1|x)} \right) = f(x) = \beta_0 + \sum_{j=1}^{m} \beta_j x_j \]

**Figure 1.5** illustrates the decision function in the two-dimensional case where both classes are linearly separable.

**Support Vector Machine**

The original support vector machine (SVM) algorithm was invented in 1963 (Vapnik and Lerner, 1963). **Figure 1.6** illustrates the main concept of this algorithm. When both classes are linearly separable, there exists an infinite number of hyperplanes that
separate both classes. The SVM algorithm finds the hyperplane that maximises the distance between the hyperplane and the closest points of both classes to the hyperplane.

The SVM algorithm was extended in 1992 to non-linear decision functions using the kernel trick (Boser et al., 1992) and in 1995 to non-strictly separable classes (Cortes and Vapnik, 1995). The general form of this algorithm is:

\[ f(x) = \alpha_0 + \sum_{i=1}^{n} \alpha_i k(x_i, x) \]

where \( k \) is the kernel. Popular kernels include:

- linear kernel: \( k(x, x') = x^\top x' \)
- polynomial kernel: \( k(x, x') = (\gamma x^\top x' + c_0)^d \) with \( c_0 \geq 0, d \in \mathbb{N}^* \)
- sigmoid kernel: \( k(x, x') = \tanh (x^\top x' + c_0) \) with \( c_0 \geq 0 \)
- RBF kernel: \( k(x, x') = \exp (-\gamma \|x - x'\|_2^2) \) with \( \gamma > 0 \)

Figure 1.7 illustrates the decision functions for these kernels. Non-linear kernels allow for more complex decision functions. This is particularly useful when the data is not linearly separable, which is the most common use case.
Figure 1.7: Impact of the kernel on the decision function of a support vector machine classifier. A non-linear kernel allows for a non-linear decision function.
1.4. Machine learning

Figure 1.8: A decision tree: (left) the rules learned by the decision tree, and (right) the corresponding decision function.

Decision Tree

A decision tree is an algorithm containing only conditional statements and can be represented with a tree-like graph (Breiman et al., 1984). This graph consists of:

- decision nodes for the first condition,
- branches for the potential outcomes of each decision node, and
- leaf nodes for the final decision.

Figure 1.8 illustrates a decision tree and its corresponding decision function. For a given sample, the final decision is obtained by following its corresponding path, starting at the root node.

Random Forest

One limitation of decision trees is that they have a low bias but a high variance. An approach to overcome this limitation is to build an ensemble of trees. In order to have trees that are not perfectly correlated, subsets of the samples and the features are considered, introducing randomness. For each decision tree, only a subset of the samples are considered, usually drawn uniformly with replacement from the whole set. For each decision node of each tree, only a subset of the features are considered to find the best split. Both characteristics explain the name given to this algorithm: random forest (Breiman, 2001).

Gradient Tree Boosting

Each tree of a random forest is built independently from the other trees. This algorithm can easily take advantage of parallelization, which is an upside. An apparent limitation
is that each tree starts the training process all over again. Boosting is a technique that sequentially trains weak algorithms and sums them to obtain a strong algorithm (Breiman, 1996). Gradient boosting is a generalization of boosting by allowing optimization of an arbitrary loss function (Breiman, 1997). Gradient boosting algorithms can be seen as iterative functional gradient descent algorithms (Friedman, 2001; Mason et al., 2000). Gradient boosting is often used with decision trees, hence the name gradient tree boosting.

More specifically, a gradient boosting algorithm is the sum of weak algorithms:

$$f(x) = f_0(x) + f_1(x) + \ldots + f_H(x) = \sum_{h=0}^{H} f_h(x)$$

and each weak algorithm is trained using functional gradient descent on the precedent weak algorithm:

$$f_h(x) = f_{h-1}(x) - \gamma_h \sum_{i=1}^{n} L(y_i, f_{h-1}(x_i))$$

$$\gamma_h = \arg \min_{\gamma} \sum_{i=1}^{n} L(y_i, f_{h-1}(x_i) - \gamma \nabla f_{h-1} L(y_i, f_{h-1}(x_i)))$$

where $L$ is the loss function that measures how good the predictions are. The lower, the better the predictions are, thus $\gamma_h$ is the argument of the minimum.

**Artificial Neural Network**

Artificial neural networks are algorithms that can be represented by a network diagram as in Figure 1.9. They consist of a sequence of layers, allowing for extraction of high-level features from structured or unstructured data. A layer is often called an artificial neuron due to its similarity with a biological neuron. The artificial neuron receives one or more inputs and combines them to produce an output. The output is analogous to the axon of a biological neuron, and its value propagates to the input of the next layer, similarly to a synapse. Like electrical circuits, layers can be connected in series or in parallel, the former being much more common than the latter. The first layer is the input layer, consisting of the input data, and the final layer is the output layer, consisting of the prediction.

Several types of layers have been developed to deal with different types of data. Fully connected layers apply a linear transformation of the input followed by a non-linear activation function. Convolutions are commonly used for images and time series because each element of the input is strongly correlated to its neighbors. Recurrent units are dedicated to sequential data as they can take as input a variable number of elements. A typical application is natural language processing, because the number of
1.4. Machine learning

words in a sentence is not constant. They can also be applied to longitudinal data.

Artificial neural networks typically have many parameters to be learned, with orders of magnitude ranging from thousands to billions of parameters. Training such algorithms is difficult as it requires a lot of data and computing power to estimate these parameters. Although research on artificial neural networks dates back to the late 1960s (Ivakhnenko and Lapa, 1967), their rise only occurred in the early 2010s. In 2012, the winning team of the ImageNet LSVRC-2010 contest used deep convolutional neural networks (Krizhevsky et al., 2012). The large increase of data and the constant progress in hardware broadened the applications of artificial neural networks and deep learning to many fields, including machine translation, object detection, image classification, chat bots, and so on.

As longitudinal cohorts naturally provide longitudinal data, the next section describes more precisely how recurrent neural networks work.

Recurrent neural networks

One of the key concepts of recurrent neural networks (RNNs) (Rumelhart et al., 1986) is sharing parameters across different parts of a model. Parameter sharing makes it possible to extend and apply the model to examples of different lengths, and generalize across them (Goodfellow et al., 2016).

A recurrent neural network is defined by the following recurrent equation

$$h^{(t)} = f(h^{(t-1)}, x^{(t)}; \theta)$$

and is illustrated in Figure 1.10. The hidden state at time $t$, $h^{(t)}$, is driven by:
Figure 1.10: Main concept of a recurrent neural network. The hidden state at time $t$, $h(t)$, is derived from the hidden state at time $t-1$, $h(t-1)$, and the external signal at time $t$, $x(t)$.

- the hidden state at time $t-1$, $h(t-1)$,
- an external signal at time $t$, $x(t)$, and
- the parameters of the RNN, $\theta$.

There is no time index for $\theta$ since $\theta$ is shared across the different time points. Intuitively, $h(t)$ represents the information extracted by the RNN at time $t$ from $(x^{(1)}, \ldots, x^{(t)})$ and is computed from:

- the information extracted by the RNN at time $t-1$, $h(t-1)$, and
- the external signal at time $t$, $x(t)$,

which simply means that the extracted information is updated based on the new observation of the external signal.

The function $f$ defines the relationship between $h(t)$, $h(t-1)$ and $x(t)$. Several functions have been developed and evaluated in the literature. We will briefly present the most used functions, often called units.

**Vanilla Recurrent Neural Network** The vanilla RNN unit was introduced by Rumelhart et al. (1986) and is illustrated in Figure 1.11. The hidden state at time $t$, $h(t)$, is a linear combination of the hidden state at time $t-1$, $h(t-1)$, and of the external signal at time $t$, $x(t)$, followed by an activation function, generally the hyperbolic tangent:

$$h(t) = \tanh \left( W_{ih}x(t) + b_{ih} + W_{hh}h(t-1) + b_{hh} \right)$$

One of the appeals of RNNs is their theoretical capability of connecting previous information to the present task. Unfortunately, the vanilla RNN unit is too simple to handle long dependencies in practice and suffers from the vanishing gradient problem.

**Long Short-Term Memory** The Long Short-Term Memory (LSTM) unit, introduced by Hochreiter and Schmidhuber (1997), was explicitly designed to avoid the long-term dependency problem and is illustrated in Figure 1.12. The LSTM unit has a
Figure 1.11: Vanilla recurrent neural network unit. The hidden state at time \( t \), \( h^{(t)} \), is a linear combination of the hidden state at time \( t - 1 \), \( h^{(t)} \), and of the external signal at time \( t \), \( x^{(t)} \), followed by an activation function.

cell state \( (C) \) and four gates \( (f, \tilde{C}, i \text{ and } o) \) that are updated at each time using the following equations:

\[
\begin{align*}
    f^{(t)} &= \sigma \left( W_{if} x^{(t)} + b_{if} + W_{hf} h^{(t-1)} + b_{hf} \right) \\
    i^{(t)} &= \sigma \left( W_{ii} x^{(t)} + b_{ii} + W_{hi} h^{(t-1)} + b_{hi} \right) \\
    o^{(t)} &= \sigma \left( W_{io} x^{(t)} + b_{io} + W_{ho} h^{(t-1)} + b_{ho} \right) \\
    \tilde{C}^{(t)} &= \tanh \left( W_{ig} x^{(t)} + b_{ig} + W_{hg} h^{(t-1)} + b_{hg} \right) \\
    C^{(t)} &= f^{(t)} \times C^{(t-1)} + i^{(t)} \times \tilde{C}^{(t)} \\
    h^{(t)} &= o^{(t)} \times \tanh \left( C^{(t)} \right)
\end{align*}
\]

The cell state is the key component of the LSTM unit. The LSTM unit has the ability to add or remove information to the cell state, carefully regulated by the gates. The forget gate \( f \) controls what the cell state must forget, while the input gate \( i \) and the candidate gate \( \tilde{C} \) regulates the new information added to the cell state. Finally, the output gate \( o \) controls which information of the cell state goes in the hidden state.

**Gated Recurrent Unit** The Gated Recurrent Unit was introduced by Cho et al. (2014) and is a variant of the LSTM unit with no output gate. The GRU has fewer parameters than the LSTM unit and has been reported to exhibit better performance on some smaller datasets (Chung et al., 2014). The GRU consists of three gates \( (r, z \text{ and } o) \)
and $\tilde{h}$) that are updated using the following equations:

$$z(t) = \sigma \left( W_{iz} x(t) + b_{iz} + W_{hz} h(t-1) + b_{hz} \right)$$

$$r(t) = \sigma \left( W_{ir} x(t) + b_{ir} + W_{hr} h(t-1) + b_{hr} \right)$$

$$\tilde{h}(t) = \tanh \left( W_{in} x(t) + b_{in} + r(t) \times \left( W_{hn} h(t-1) + b_{hn} \right) \right)$$

$$h(t) = \left( 1 - z(t) \right) \times h(t-1) + z(t) \times \tilde{h}(t)$$

The reset gate $r$ allows for resetting the hidden state with the observation $x$, creating the candidate gate $\tilde{h}$. The update gate $z$ allows for updating the hidden state with the candidate gate $\tilde{h}$.

### 1.4.3 Regularization

Most machine learning algorithms are trained by minimizing a cost function:

$$\min_{\theta} c(\theta)$$

The cost function $c$ measures the difference between the predictions of the algorithm and the true values of the target. The lower the loss function, the better the predictions. Fitting the training data consists in iteratively updating the parameters of the algorithm $\theta$ to minimize the loss function. However, if the model is too complex, its error on the training set is much lower than on the test, that is generalization (replication) on new
observations is suboptimal. This phenomenon is known as overfitting (see Figure 1.14).

A common approach to avoid overfitting is to add a regularization term in the cost function that limits the complexity of the model:

$$\min_\theta c(\theta) + \lambda \times \text{Reg}(\theta)$$

The value of $\lambda$ corresponds to the weight of the regularization in the loss function: the higher, the lower the complexity of the model. To illustrate the effect of regularization, we generate a toy data set from the following distributions (see Figure 1.15 for an example of a generated data set with 100 points):

$$x \overset{iid}{\sim} \mathcal{U}_{[0,10]}$$

$$y \sim \mathcal{N}(\sin(x), 0.5)$$

A kernel ridge regression algorithm (Murphy, 2012) is trained on this data set for different values of $\lambda$ (see Figure 1.16). When the value of $\lambda$ is too high, the model does not fit the data enough (underfitting). When the value of $\lambda$ is too low, the model fits the data too much (overfitting). An appropriate trade-off between fitting the data and limiting the complexity of the model gives the best results. This is known as the
Figure 1.14: Relationship between error and model complexity. A too low complexity leads to underfitting. A too high complexity leads to overfitting.

Figure 1.15: Toy regression data set with a non-linear relationship.
bias-variance trade-off. If the loss function is the squared difference between the true value $y$ (fixed) and the predicted value $\hat{y}$ (random variable), then its expected value is the sum of the squared bias of $\hat{y}$ and its variance:

$$
\mathbb{E} [(y - \hat{y})^2] = \mathbb{E} [y^2 - 2y\hat{y} + \hat{y}^2] \\
= y^2 - 2y\mathbb{E} [\hat{y}] + \mathbb{E} [\hat{y}^2] \\
= y^2 - 2y\mathbb{E} [\hat{y}] + \mathbb{E} [\hat{y}^2] + \mathbb{E} [\hat{y}]^2 - \mathbb{E} [\hat{y}]^2 \\
= (\mathbb{E} [\hat{y}] - y)^2 + \mathbb{E} [\hat{y}^2] - \mathbb{E} [\hat{y}]^2 \\
= (\mathbb{E} [\hat{y}] - y)^2 + \mathbb{E} [(\hat{y} - \mathbb{E} [\hat{y}])^2] \\
\mathbb{E} [(y - \hat{y})^2] = (\mathbb{E} [\hat{y}] - y)^2 + \mathbb{V} [\hat{y}]
$$

When the model does not capture the regularities of the data, its bias is high but its variance is low (underfitting). When the model captures the noise of the data, its bias is low but its variance is high (overfitting).

The most common regularization terms for structured (tabular) data are the $\ell_2$-penalty, $\ell_1$-penalty, and the elastic net.

$\ell_2$-penalty

The $\ell_2$-penalty of $\theta$ is the squared $\ell_2$-norm of $\theta$, that is the sum of the squared elements in $\theta$:

$$
\ell_2(\theta) = \|\theta\|^2 = \sum_i \theta_i^2
$$

Adding this term to the loss function has several advantages: (i) it makes the optimization problem strictly convex; (ii) it forces each value $\theta_i$ not to be too large; (iii) for linear models, the coefficients become more robust to collinearity. Linear regression with $\ell_2$-penalty is commonly known as ridge regression (Tikhonov et al., 1977):

$$
\min_\beta \|y - X\beta\|^2_2 + \lambda \|\beta\|^2_2
$$

$\ell_1$-penalty

The $\ell_2$-penalty forces the values of the parameters not to be too large, but does not incentive to make small values tend to 0. Indeed, the square of a small value is even smaller. When the number of features is large, or when interpretability is important,
Figure 1.16: Illustration of regularization. A kernel ridge regression algorithm is fitted on this data with different values of \( \lambda \), which is the weight of the regularization in the loss function. The smaller values of \( \lambda \), the smaller the weight of the \( \ell_2 \) regularization. The algorithm underfits (respectively overfits) the data when the value of \( \lambda \) is too large (respectively low).
Figure 1.17: Unit balls of the $\ell_0$, $\ell_1$ and $\ell_2$ norms. For each norms, the set of points in $\mathbb{R}^2$ whose norm is equal to 1 is plotted. The $\ell_1$ norm is the best convex approximation to the $\ell_0$ norm. Note that the lines for the $\ell_0$ extend to $-\infty$ and $+\infty$, but are cut for plotting reasons.

it can be useful to make the algorithm select the most important features. The corresponding norm is the $\ell_0$-norm, defined as the number of nonzero elements:

$$\ell_0(\theta) = \|\theta\|_0 = \sum_i 1(\theta_i \neq 0)$$

However, the $\ell_0$-norm is not differentiable and not convex. The best convex approximation of the $\ell_0$-norm is the the $\ell_1$-norm (see Figure 1.17), defined as the sum of the absolute values of each element:

$$\ell_1(\theta) = \|\theta\|_1 = \sum_i |\theta_i|$$

Linear regression with $\ell_1$-penalty is commonly known as LASSO (Tibshirani, 1996):

$$\min_\beta \|y - X\beta\|^2_2 + \lambda \|\beta\|_1$$

**Elastic net**

The $\ell_1$-penalty has several limitations. When the number of features is larger than the number of samples, the LASSO selects at most $n$ variables before it saturates. When there is a group of highly correlated variables, the LASSO tends to select only one variable from a group and ignore the others (Zou and Hastie, 2005).

To overcome these limitations, the elastic net penalty linearly combines the $\ell_2$- and
\( \ell_1 \)-penalties to get the best of both penalties (Zou and Hastie, 2005):

\[
\text{EN}(\theta) = \lambda \|\theta\|_2^2 + \nu \|\theta\|_1
\]

### 1.4.4 Metrics

Metrics are a key component of machine learning as they evaluate how well models perform. There exist many ways of evaluating models, and choosing metrics must be based on the most important evaluation criteria, which depend on the task. In this section we will present the two metrics that we chose to evaluate the algorithms: the area under the receiver operating characteristic curve and the average precision. But first, we provide some reminder on binary classification and introduce the confusion matrix.

**Confusion matrix**

For classification tasks, a confusion matrix is matrix that reports all the possible combinations between the predicted output and the true output. Each row consists of the true classes, while each column consists of the predicted classes. For binary classification tasks, the four entries are known as:

- True positives (\( TP \)): the true class and the predicted class are both positive;
- False positives (\( FP \)): the true class is negative, and the predicted class is positive;
- True negatives (\( TN \)): the true class and the predicted class are both negative;
- False negatives (\( FN \)): the true class is positive, and the predicted class is negative.

Table 1.1 illustrates the concept of the confusion matrix for binary classification tasks, and the most common statistics derived therefrom. Since most of these statistics have several names, we recall them to avoid any confusion:

- True positive rate = Sensitivity = Recall = \( \frac{TP}{TP + FN} \)
- True negative rate = Specificity = \( \frac{TN}{TN + FP} \)
- Positive predictive value = Precision = \( \frac{TP}{TP + FP} \)
- Negative predictive value = \( \frac{TN}{TN + FN} \)

The true positive rate (TPR), also known as sensitivity or recall, is the proportion of true positives among all the positives. The true negative rate (TNR), also known as specificity, is the proportion of true negatives among all the negatives. The positive predictive value (PPV), also known as precision, is the proportion of true positives
### 1.4. Machine learning

<td>TN</td>
</tr>
</tbody>
</table>

\[
\text{TPR} = \frac{TP}{TP + FN} \\
\text{TNR} = \frac{TN}{TN + FP} \\
\text{PPV} = \frac{TP}{TP + FP} \\
\text{NPV} = \frac{TN}{TN + FN}
\]

Table 1.1: Confusion matrix for binary classification. Each row represents the true positive and negative classes. Each column represents the predicted positive and negative classes. The entries of the confusion matrix correspond to all the possible outcomes. 

TP: True positives; FN: False negatives; FP: False positives; TN: True negatives; TPR: True positive rate; TNR: True negative rate; PPV: Positive predictive value; NPV: Negative predictive value.

among all the predicted positives. The negative predictive value (NPV) is the proportion of true negatives among all the predicted negatives.

A perfect classifier is classifier with no error, that is such that \( FN = FP = 0 \). For instance, a classifier is perfect if and only if:

- \( \text{TPR} = \text{TNR} = 1 \) since \( \text{TPR} = 1 \iff FN = 0 \) and \( \text{TNR} = 1 \iff FP = 0 \)
- \( \text{TPR} = \text{PPV} = 1 \) since \( \text{TPR} = 1 \iff FN = 0 \) and \( \text{PPV} = 1 \iff FP = 0 \)

Except if the binary classification task is relatively easy, having a perfect classifier is extremely rare. Sometimes, the scores of a classifier, such as probabilities, are as important as the predicted classes. For instance, clinicians are often more interested in the risks (i.e. probabilities) of a given disorder, rather than just a prediction. As a reminder, most binary classification algorithms consist of two steps:

1. Computing a score \( f(x) \) for sample \( x \)
2. Deriving the predicted class from the score \( f(x) \) using a threshold \( \epsilon \):

\[
\hat{y} = \begin{cases} 
+1 & \text{if } f(x) > \epsilon \\
-1 & \text{if } f(x) < \epsilon 
\end{cases}
\]

For linear classifiers, \( f(x) = \beta_0 + \sum_{j=1}^{m} \beta_j x_j \) represents the signed distance to the hyperplane. Instead of comparing the true classes and the predicted classes

\[
y = (y_1, \ldots, y_n) \quad , \quad \hat{y} = (\hat{y}_1, \ldots, \hat{y}_n)
\]
one can compare the true classes and the scores

\[ y = (y_1, \ldots, y_n), \quad f(X) = (f(x_1), \ldots, f(x_n)) \]

Two popular metrics to compare the true classes and the scores are the *area under the receiver operating characteristic curve* (ROC AUC), derived from the receiver operating characteristic (ROC) curve, and the *average precision* (AP) score, derived from the precision-recall (PR) curve.

**Receiver operating characteristic curve**

The receiver operating characteristic curve is the plot representing the true positive rate against the false positive rate at various threshold settings. The false positive rate is the proportion of false positives among all the negatives and can be calculated as \((1 - \text{specificity})\). The ROC curve starts at \((0, 0)\), when all the samples are predicted negatives \((\text{TPR} = 1 - \text{TNR} = 0)\), and ends at \((1, 1)\), when all the samples are predicted positives \((\text{TPR} = 1 - \text{TNR} = 1)\). The ROC curve is non-decreasing because no sample which is classified as a negative will ever be classified as a positive for any higher threshold.

The area under the ROC curve summarizes the ROC curve with a single score. ROC AUC can be computed as

\[
\text{ROC AUC} = \frac{1}{n_{+1} \times n_{-1}} \sum_{i=1}^{n} \sum_{j=1}^{n} \mathbb{1}(f(x_i) > f(x_j))
\]

where \(n_{+1}\) and \(n_{-1}\) are the number of positives and negatives respectively. ROC AUC has a simple interpretation: it is the probability that the classifier ranks a randomly chosen positive sample higher than a randomly chosen negative one. ROC AUC has the following properties:

- It is always between 0 and 1;
- The higher, the better;
- ROC AUC = 0 if and only if all the negative samples have higher scores than all the positive samples;
- ROC AUC = 1 if and only if all the positive samples have higher scores than all the negative samples (i.e. there exists a threshold yielding a perfect classifier);
- The expected ROC AUC of random guess is 0.5, independently of the distribution of the classes.
1.4. Machine learning

Precision-recall curve

The precision-recall curve is the plot representing the precision against the recall at various threshold settings. Since the recall is the true positive rate, the only difference with the ROC curve is the replacement of the false positive rate with the precision. The PR curve starts at (0, 1), when all the samples are predicted negatives (TPR = 0, PPV = 1), and ends at (1, p), when all the samples are predicted positives (TPR = 1, PPV = p), p being the prevalence of the positive class. Precision is actually ill-defined when all the samples are predicted negatives (both the numerator and denominator are equal to 0), but the precision is expected to tend to 1 when the number of predicted positive samples tend to 0.

Contrary to the ROC curve, which takes into account the four possible outcomes (TP, FN, TN, FP), the precision-recall curve does not take into account the true negatives. Intuitively, precision is the ability of the classifier not to label as positive a sample that is negative, and recall is the ability of the classifier to find all the positive samples. The PR curve measures how well the classifier finds all the positive samples without labeling negative samples as positives.

The precision-recall curve is particularly useful for rare event detection, where false negatives are much more serious than false positives. For instance, let’s consider a low-cost, fast, non-invasive diagnostic test for a serious disease. If this test is positive, the subject have a more advanced, costly, invasive exam to confirm the diagnosis. If this test is negative, the subject will have another test in a few years. We would like this test to find all the subjects with this disease while labeling the least healthy subjects as ill. Finding the healthy subjects is of much smaller interest than finding the ill ones.

The average precision score summarizes a precision-recall curve as the weighted mean of precisions achieved at each threshold, with the increase in recall from the previous threshold used as the weight:

\[
AP = \sum_k (R_k - R_{k-1})P_k
\]

where \(P_k\) and \(R_k\) are respectively the precision and recall at the \(k\)-th threshold. Average precision is also the area under the precision-recall curve, but computed with a different technique than the one used to compute ROC AUC. AP is the area under the PR curve computed using the Riemann integral, while ROC AUC is the area under the ROC curve computed using the trapezoidal rule. A linear interpolation (with the trapezoidal rule) of points on the precision-recall curve provides an overly-optimistic measure of classifier performance (Davis and Goadrich, 2006; Flach and Kull, 2015). AP has the following properties:

- It is always between 0 and 1;
- The higher, the better;
Figure 1.18: Receiver operating characteristic and precision-recall curves. The curves are represented in blue, and the expected curves of random guess are highlighted in red. The area under the ROC curve is computed with the trapezoidal rule, while the average precision score is the area under the PR curve computed with the Riemann integral.

- AP = 1 if and only if all the positive samples have higher scores than all the negative samples (i.e. there exists a threshold yielding a perfect classifier);

- The expected AP of random guess is equal to $p$, the prevalence of the positive class.

Figure 1.18 illustrates the ROC and PR curves. On the ROC curve, the lower the threshold, the higher the true positive and negative rates. The PR curve does not have a monotonicity property, as precision can increase when recall increases. Expected curves of random guess are highlighted.

1.5 Putting it all together

Given the association between impulse control disorders in Parkinson’s disease and potential medical, financial, and/or legal medical complications, worse quality of life and function, high rates of psychiatric comorbidity, and strained interpersonal relationships and caregiver burden, identification and treatment of the symptoms are typically imperative (Weintraub and Claassen, 2017). Accurate prediction of ICDs ahead of time may allow avoiding their potentially terrible consequences and would enable to keep prescribing dopamine agonists with less fear of their adversarial effects.

Most of the literature on ICDs in PD is focused on associations, that is features that are correlated with ICDs, in cross-sectional studies. These associations, although important, have important limitations:
Since these associations are cross-sectional, they may not hold true to predict ICDs in advance;

- Associations may be correlated, so that finding a new association may not be helpful to predict ICDs;
- Even new uncorrelated associations may not be helpful to predict ICDs.

Knowing associated factors may not be enough to prevent the irreversible consequences of ICDs. One of the earliest studies on pathological gambling in PD reported losses of hundreds of thousands of dollars for several patients (Gschwandtner et al., 2001). Being able to predict ICDs in advance could help preventing these life-changing events. A couple of studies focused on predicting ICDs, but the lack of cross-validation, that is evaluating a model on different data than the data used to train the algorithm, affects the confidence in their results.

Being able to accurately predict ICDs in advance would be of great interest clinically. Managing ICDs is not an easy task, as patients may not be aware of their behaviors, or can lie to their relatives and clinicians. Raising awareness in PD patients and their relatives would be more impactful if they could be told precisely when ICDs will be developed. ICDs may even be prevented, as case reports suggest that ICDs often resolve after reducing the dose of the existing dopamine agonists, in particular with complete discontinuation of DA treatment (Weintraub and Claassen, 2017).

Moreover, the genetic factors of ICDs in PD are mostly unknown. A few associations from candidate gene analyses have been reported, but these studies have not been replicated. Using machine learning algorithms to learn genetic factors from the whole genome, instead of picking a few genes based on prior information, may shed some new light on these genetic factors.

The interaction between putative genetic factors and clinical risk factors is also unknown, and may play an important role for the onset of ICDs in PD. Investigating different approaches modelling different types of interaction may help better understanding these disorders.

The association between known factors and impulse control disorders is complex (Grall-Bronnec et al., 2018). Impulse control disorders have been mainly studied from the statistical point of view, and machine learning has been underused. Machine learning, by automatically extracting information from data, could improve the predictability of ICDs and leverage the knowledge on this topic, but also improve the quality of life of patients and decrease caregiver burden.

1.6 Materials

Data analysis requires two essential components: data sets, to provide data, and software, to analyze data. Data sets can be private or publicly available, the former being
much more common than the latter in medicine. Software, by providing implementations of algorithms and utility tools, are at the core of data analysis.

In this section, we present the data sets from which we obtained data, and the software that we used to perform the analysis of these data.

1.6.1 Data sets

Medical data sets are not easy to collect and share for ethical, legal and privacy reasons. Nonetheless, data sets are needed to better understand disorders and to further advance scientific knowledge. In particular, publicly available data sets are very relevant because they give anyone access to data, regardless of their institution or employer. They also allow for tackling the reproducibility crisis that science is currently facing. Their main drawback is their possible overuse, leading to biases in the results.

In our work, we used two data sets: the Parkinson’s Progressive Markers Initiative (PPMI) database and the Drug Interaction With Genes in Parkinson’s Disease (DIGPD) database.

**Parkinson’s Progressive Markers Initiative**

In the field of Parkinson’s disease therapeutics, the ultimate goal is to develop disease-modifying treatments that slow, prevent or even reverse the underlying disease process. Validated biomarkers of disease progression would dramatically accelerate PD therapeutics research. However, current progression biomarkers are not optimal and are not fully validated.

The Parkinson’s Progression Markers Initiative (www.ppmi-info.org) is a landmark observational clinical study to comprehensively evaluate cohorts of significant interest using advanced imaging, biologic sampling and clinical and behavioral assessments to identify biomarkers of Parkinson’s disease progression. PPMI is taking place at clinical sites in the United States, Europe, Israel, and Australia (see Table 1.2 for the full list of clinical sites).

Data and samples acquired from study participants enable the development of a comprehensive Parkinson’s database and biorepository, which is currently available to the scientific community to conduct field-changing research. PPMI follows standardized data acquisition protocols to ensure that tests and assessments conducted at multiple sites and across multiple cohorts can be pooled in centralized databases and repositories. The clinical, imaging and biologic data is easily accessible to researchers in real time through their website.

**Drug Interaction With Genes in Parkinson’s Disease**

The Drug Interaction With Genes in Parkinson’s Disease study is a longitudinal cohort study of patients with PD consecutively recruited from May 2009 to July 2013 in 4

French university hospitals and 4 general hospitals (Corvol et al., 2018). Eligible patients were patients with PD (UK Parkinson’s Disease Society Brain Bank criteria) with disease duration shorter than 5 years at recruitment. After the baseline visit, annual clinical evaluations were performed over 5 years by movement disorders specialists who checked whether patients still fulfilled UK Parkinson’s Disease Society Brain Bank criteria at each visit and filled out standardized questionnaires. All patients had a blood sampling for DNA extraction and genome-wide genotyping. The study was conducted according to Good Clinical Practice Guidelines, and sponsored by Assistance Publique Hôpitaux de Paris. All patients provided informed consent, and the study was approved by local ethical committee and regulation authorities.

Assessed phenotypes

Parkinson’s disease is characterized by a wide range of symptoms. In order to diagnose them and assess their severity, screening tools and rating scales are used. General screening tools are often administered, but questionnaires and scales specific to Parkinson’s disease have also been developed.

For most phenotypes, several screening tools are available. Apart from the Movement Disorder Society-sponsored revision of the Unified Parkinson’s Disease Rating Scale, which quantifies the severity of Parkinson’s disease, there is no real consensus on the scales to use, and different databases may use different scales to assess some phenotypes. These differences can cause some issues for machine learning algorithms that expect the same features in the sets used to train and evaluate the models. Table 1.3 lists the questionnaires and scales used in PPMI and DIGPD for the main symptoms of Parkinson’s disease. Several symptoms that have been associated with impulse control disorders, such as anxiety and depression, are assessed with different scales in both databases.

1.6.2 Software

We describe in this section the software that we used, grouped by programming languages: Python for machine learning, C/C++ for genetic analyses, and R for meta-analysis.

Python

Python (Van Rossum and Drake, 2009) is a programming language that is easy to pick up regardless of past programming experience. Python is developed under an open source license, making it freely usable and distributable, even for commercial use. Python has a large community of users and developers, with over two hundred and fifty thousand projects referenced on the Python Package Index (https://pypi.org).

A large part of the growing popularity of Python is due to the increasing interest in data science and the availability of maintained, well-documented, high-quality Python packages for science. From data manipulation to machine learning to data visualization, Python is the de facto programming language for data science. We will briefly introduce the packages that we used to perform analyses.

**NumPy** `numpy` ([Harris et al., 2020a](#)) is the fundamental package for scientific computing with Python. Fast and versatile, the NumPy vectorization, indexing, and broadcasting concepts are the standards of array computing today. `numpy` offers many numerical computing tools: comprehensive mathematical functions, random number generators, linear algebra routines, Fourier transforms, and more.

**SciPy** `scipy` ([Virtanen et al., 2020](#)) is a package dedicated to scientific computing. It provides many user-friendly and efficient numerical routines, such as routines for numerical integration, interpolation, optimization, linear algebra, and statistics, as well as sparse matrices.

**pandas** `pandas` ([McKinney, 2010](#)) is a fast, powerful, flexible and easy to use open source data analysis and manipulation tool. It provides tools for reading and writing data, fast and efficient data manipulation, and high performance merging and joining of data sets.
**Statsmodels** statsmodels (Seabold and Perktold, 2010) is a Python module that provides classes and functions for the estimation of many different statistical models. It also provides utilities to conduct statistical tests and statistical data exploration.

**UMAP** UMAP (McInnes et al., 2018) is a Python package providing an implementation of the Uniform Manifold Approximation Projection (UMAP) algorithm, which is a popular dimension reduction techniques that can be used for visualization but also for general non-linear dimension reduction (McInnes et al., 2018).

**Scikit-learn** scikit-learn (Pedregosa et al., 2011) is a popular package for machine learning in Python. It is a versatile toolbox for data mining and data analysis, making available numerous machine learning algorithms and utility tools under a unified application programming interface. scikit-learn is easily accessible to everybody and usable in various contexts.

**XGBoost** xgboost (Chen and Guestrin, 2016) is an optimized distributed gradient boosting library designed to be highly efficient, flexible and portable. xgboost implements machine learning algorithms under the gradient boosting framework that solve many data science problems in a fast and accurate way.

**PyTorch** pytorch (Paszke et al., 2019) is an open source machine learning framework dedicated to deep learning. A rich ecosystem of tools and libraries extends pytorch and supports development in computer vision, natural language processing and more.

**Matplotlib** matplotlib (Hunter, 2007) is a comprehensive library for creating static, animated, and interactive visualizations in Python. Several toolkits are available which extend matplotlib functionality.

**C/C++**

C is a general-purpose programming language that is widely used for systems programming in implementing operating systems and embedded system applications. C++, an extension of C, was designed with performance, efficiency, and flexibility as its core.

Thanks to low overhead, C and C++ enable programmers to create efficient implementations of algorithms and data structures, useful for computationally intense programs. Most of the Python packages with intensive computations are partially written in C or one of its variants under the hood. Nonetheless, some scientific libraries are completely written in C/C++, in particular for genetic analyses.
PLINK  PLINK (Chang et al., 2015) is a widely used C/C++ tool set for research in population genetics and genome-wide association studies. PLINK provide utilities for data management, basic statistics, linkage disequilibrium calculation, population stratification, association analysis, and tests for epistasis.

GCTA  GCTA (Yang et al., 2011) is a C/C++ tool for genome-wide complex trait analysis. GCTA was initially designed to estimate the proportion of phenotypic variance explained by all genome-wide single SNPs for complex traits. It has been subsequently extended for many other analyses to better understand the genetic architecture of complex traits, such as estimation of SNP-based heritability and genomic risk prediction.

R  
R is a popular programming language for statistical computing and many packages have been developed to perform statistical analyses. R provides a wide variety of statistical (linear and nonlinear modelling, classical statistical tests, time-series analysis, classification, clustering, etc.) and graphical techniques, and is highly extensible.

meta  meta (Balduzzi et al., 2019) is a user-friendly general package providing standard methods for meta-analysis. meta provides fixed effects and random effects models and several plots for meta-analysis among other tools.
Chapter 2

Prediction of impulse control disorders in Parkinson’s disease

This chapter has been submitted to the *Annals of Neurology* journal as:

**Johann Faouzi**, Samir Bekadar, Baptiste Couvy-Duchesne, Fanny Artaud, Alexis Elbaz, Graziella Mangone, Olivier Colliot and Jean-Christophe Corvol. “Prediction of impulse control disorders in Parkinson’s disease”.

Abstract

**Objective** To predict the (future) occurrence of impulse control disorders (ICDs) in Parkinson’s disease (PD) using longitudinal data, the first study using cross-validation and replication in an independent cohort.

**Methods** We included data from two longitudinal PD cohorts (training set: PPMI, Parkinson’s Progression Markers Initiative; replication: DIGPD, Drug Interaction With Genes in Parkinson’s Disease). Patients with at least two visits and with genetic data available were included into the analysis. We trained three logistic regressions and a recurrent neural network to predict ICD at the next visit using clinical risk factors and genetic variants previously associated with ICDs. We quantified performance using the area under the receiver operating characteristic curve (ROC AUC) and average precision.

**Results** We included 380 PD subjects (2,728 visits) from PPMI and 388 PD subjects (2,101 visits) from DIGPD in our analyses. The number of patients presenting ICDs during follow-up were 143 (38%) in PPMI and 192 (49%) in DIGPD. All the models performed relatively well at predicting the ICDs at the next visit (PPMI: ROC AUC = 0.81 [0.75 - 0.85], DIGPD: ROC AUC = 0.77 [0.67 - 0.80]). Taking previous data from all visits into account improved the predictive performance (PPMI: ROC AUC = 0.83 [0.80 - 0.85], DIGPD: ROC AUC = 0.80 [0.80 - 0.80]), as compared to only using
the baseline visit (PPMI: ROC AUC = 0.75, DIGPD: ROC AUC = 0.67). Recurrent neural networks did not improve the predictive performance.

**Interpretation** ICDs in PD can be predicted with acceptable accuracy, which may be used to improve the management of PD patients and diminish the potentially devastating impacts of ICDs.

### 2.1 Introduction

Although Parkinson’s disease (PD) is mostly known for its motor symptoms, numerous non-motor symptoms have been reported to occur during the course of the disease (Hiseman and Fackrell, 2017). Impulse control disorders (ICDs), a class of psychiatric disorders characterized by impulsivity, are common in PD, with half of PD cases expected to experience some of them by 5 years after disease onset (Corvol et al., 2018). The four most common ICDs in PD are pathological gambling, compulsive eating, hypersexuality, and compulsive eating disorder. ICDs are associated with reduced quality of life, strained interpersonal relationships, increased caregiver burden, and require prompt addressing (Weintraub and Claassen, 2017). Several case reports suggest that partial and total discontinuations of dopamine agonist (DA) treatment leads to a resolution of ICDs (Mamikonyan et al., 2008; Nirenberg and Waters, 2006).

Many factors have been associated with ICDs in PD, including socio-demographic, clinical and genetic biomarkers (Grall-Bronnec et al., 2018). In particular, men tend to develop more pathological gambling and hypersexuality disorders while women develop more compulsive buying and eating disorders (Weintraub and Claassen, 2017). A younger age has been associated with ICDs in PD in numerous studies (Callesen et al., 2014; Poletti et al., 2013; Pontieri et al., 2015; Weintraub et al., 2010a). Anxiety (Leroi et al., 2012; Pontieri et al., 2015; Voon et al., 2011), depression (Callesen et al., 2014; Voon et al., 2011), and rapid eye movement (REM) sleep behavior disorders (Fantini et al., 2015; Ramírez Gómez et al., 2017) have also been correlated to ICDs. Dopamine replacement therapy, in particular dopamine agonists, has been strongly associated with ICDs. Finally, associations between ICDs and several single-nucleotide polymorphisms (SNPs) in dopamine signaling pathway genes have been suggested (Castro-Martínez et al., 2018; Cormier-Dequaire et al., 2018; Erga et al., 2018; Krishnamoorthy et al., 2016; Lee et al., 2009; Zainal Abidin et al., 2015).

The predictive performance of these factors altogether has been underexplored. Only two studies report predictions at the patient level (Erga et al., 2018; Kraemmer et al., 2016). In both studies, authors trained a logistic regression using clinical and genetic data, and measured its predictive performance using the area under receiver operating characteristic (ROC) curve (ROC AUC). None of these studies had cross-validation or a replication cohort, altering the confidence in the reported performance (Koul et al., 2018).
Our main objective was to predict ICDs from clinical and genetic using machine learning approaches. We utilized two longitudinal cohorts to train and cross-validate the models on one cohort, but also assess the generalization capability of these models on the second cohort. The objective was to predict the risk of ICDs at the next visit, knowing the clinical history of the patient and their genotyping data.

2.2 Materials and methods

2.2.1 Populations

We used data from two research cohorts: the Parkinson’s Progression Markers Initiative (PPMI) database and the Drug Interaction With Genes in Parkinson’s Disease (DIGPD) study.

PPMI (https://www.ppmi-info.org) is a multicenter observational clinical study using advanced imaging, biologic sampling, and clinical and behavioral assessments to identify biomarkers of PD progression (Marek et al., 2011). Data was gathered during face-to-face visits every 6-12 months. PD subjects were de novo and drug-naïve at baseline. We downloaded the clinical and genetic data from the PPMI database (https://www.ppmi-info.org/data) on the 17th of October, 2019.

DIGPD is a French multicenter longitudinal cohort with annual follow-up of PD patients (Corvol et al., 2018). Eligible criteria consist in recent PD diagnosis (UK Parkinson’s Disease Society Brain Bank criteria) with disease duration less than 5 years at recruitment. Data was gathered during face-to-face visits every 12 months following standard procedures.

Both studies were conducted according to good clinical practice, obtained approval from local ethic committees and regulatory authorities, and all patients provided informed consent prior to inclusion.

2.2.2 Participants and clinical measurements

Inclusion criteria consisted of having: (i) a PD diagnosis, (ii) a baseline visit and at least another visit, (iii) clinical and genetic data available, and (iv) PD medication taken available.

We included socio-demographics and clinical variables that have been associated with ICDs in the literature: age of PD onset, length of follow-up, sex, past ICDs, continuous scales of anxiety, depression and REM sleep, and the motor exam (part III) of the Movement Disorders Society-sponsored revision of the Unified Parkinson’s Disease Rating Scale (MDS-UPDRS). ICDs were assessed at each visit using the Questionnaire for Impulsive-Compulsive Disorders in Parkinson’s Disease - Rating Scale (Weintraub et al., 2012) in PPMI, and through semi-structured interviews by a movement disorder specialist in DIGPD. We standardized each feature since some of them were assessed
with different scales and because it is a common requirement for most machine learning estimators.

We took into account PD medication with three binary variables corresponding to the main classes of treatment (levodopa, dopamine agonists, others) and we derived more specific variables for dopamine agonists: mean daily, maximum daily and total doses (expressed in levodopa equivalent) and cumulative duration.

### 2.2.3 Genetic variants

In absence of genome-wide association study on ICDs in PD, we considered 50 genetic variants selected as previously described: 20 variants from 16 genes involved in dopamine, serotonin, glutamate, norepinephrine and opioid systems and previously associated with ICD in PD or in the general population (Cormier-Dequaire et al., 2018); 30 additional variants from 10 genes differentially expressed after an acute challenge of levodopa in the striatum in a mouse model of dopamine denervation (Charbonnier-Beaupel et al., 2015).

Genotyping data were collected using NeuroX (Nalls et al., 2015) arrays in PPMI (267,607 variants measured), and Illumina Multi-Ethnic Genotyping Arrays in DIGPD (1,779,819 variants). We excluded variants with missing rates greater than 2% and variants deviating from Hardy-Weinberg equilibrium ($p < 10^{-8}$). We excluded related individuals (third-degree family relationships), individuals with mismatch between reported sex and genetically determined sex, and individuals with outlying heterozygosity ($\pm 3$ standard deviation). We imputed missing SNPs using the Michigan Imputation Server (Das et al., 2016) for PPMI and the Sanger Imputation Server (McCarthy et al., 2016) for DIGPD, using the reference panel of the Haplotype Reference Consortium (release 1.1) (McCarthy et al., 2016). We filtered variants based on their imputation quality ($R^2 > 0.6$ for PPMI, INFO score $> 0.9$ for DIGPD).

### 2.2.4 Data processing

Processing genetic data and extracting variants of interest matching inclusion criteria was performed using the PLINK (Chang et al., 2015) software. Processing of the different text-like files was performed using the pandas (McKinney, 2010) and NumPy (Harris et al., 2020a) Python packages. Missing values were imputed in a forward-fill fashion: for a given subject and a given feature, missing values were imputed using the most recent non-missing value for this subject and this feature. Baseline missing values were imputed using the mean baseline values on the training set.

### 2.2.5 Machine learning algorithms

We investigated five standard machine learning algorithms implemented in the scikit-learn (Pedregosa et al., 2011) and XGBoost (Chen and Guestrin, 2016) Python packages:
2.2. Materials and methods

![architecture_diagram](image)

Figure 2.1: Architecture of the recurrent neural network. The clinical features assessed at several visits are used as input of the Gated Recurrent Unit (GRU). The GRU extracts information from these clinical features into a vector \( h(t) \). This vector and the time-independent variables, namely the socio-demographic and genetic data denoted as \( s \), are used as input of a Fully Connected (FC) function followed by a sigmoid activation, returning the probability of having an impulse control disorder at the next visit.

As the prediction task is longitudinal, we also investigated the use of recurrent neural networks. Recurrent neural networks are a class of artificial neural networks dedicated to sequential data. We employed a simple architecture (Figure 2.1) with a Gated Recurrent Unit (Cho et al., 2014) to extract information from the clinical measurements, followed by a concatenation of this vector with the socio-demographic and genetic data, followed by a Fully Connected function with a sigmoid activation. We use the PyTorch (Paszke et al., 2019) Python package to build and train the recurrent neural network.
2.2.6 Cross-validation

We used PPMI as the training (discovery) cohort, and DIGPD as the testing (replication) cohort. To unbiasedly estimate the predictive performance of the models, we employed a nested cross-validation procedure that is illustrated in Figure 2.2. In the outer loop, we randomly split 80% of the PPMI subjects into the training set and the remaining 20% into the test set. In the inner loop, we performed a 5-fold subject-level cross-validation procedure to optimize the hyper-parameters of the models on the training set. These hyper-parameters control how the algorithms fit the training data. For instance, these hyper-parameters included the type (l1 or l2 penalty) and amount (lambda parameter) of regularization for the linear models. In particular, logistic regression models were regularized. After finding the optimal values for the hyper-parameters, each model was evaluated on the test set. Finally, we evaluated the performance of each model on the whole DIGPD cohort.

2.2.7 Statistical analysis

Baseline characteristics in both cohorts were compared with chi-squared tests for categorical variables and t-tests for continuous variables using the SciPy (Virtanen et al., 2020) Python package. Predictive performance was mainly evaluated using the area under the receiver operating characteristic curve and average precision (AP). AP summarizes a precision-recall curve as the weighted mean of precisions achieved at each
threshold, with the increase in recall from the previous threshold used as the weight. The precision-recall curve is similar to the ROC curve, but plots the precision (positive predictive value) against the recall (sensitivity). The precision-recall curve does not take into account the true negatives, and is particularly useful when the positives are more important than the negatives (false negatives are more serious than false positives). Other metrics included accuracy, balanced accuracy, sensitivity and specificity. ROC and precision-recall curves were plotted using the matplotlib (Hunter, 2007) Python package, and all the metrics were computed using the scikit-learn (Pedregosa et al., 2011) package. Comparison between ROC AUC was measured using DeLong test (DeLong et al., 1988). P-values were adjusted for multiple comparisons using Bonferroni correction. We did not statistically compare AP scores as we were not aware of a relevant statistical test to do so, and reported 95% confidence intervals using bootstrapping.

2.3 Results

2.3.1 Population characteristics

Out of the 423 PD subjects in PPMI, we excluded 1 subject for not having a baseline visit, 2 for not having medication records and 40 for not having genetic data. Out of the 415 PD subjects in DIGPD, we excluded 27 for having only a baseline visit. No subjects were excluded based on their genetic data. Thus, we included 380 PD subjects from PPMI and 388 PD subjects from DIGPD in our analyses. The 380 PPMI subjects had a total of 2,728 visits, while the 388 DIGPD subjects had a total of 2,101 visits. Since our objective was to predict the occurrence of ICDs at the next visit, the number of observations for a given subject is equal to their number of visits minus 1. Thus, the total number of observations was equal to 2,348 in PPMI and 1,713 in DIGPD.

Clinical characteristics are presented in Table 2.1. Age and sex in both cohorts were not significantly different. PPMI subjects had significantly more visits and smaller intervals between back-to-back visits, as well as longer follow-ups. DIGPD subjects had significantly lower scores in the motor exam of the MDS-UPDRS. The prevalence of ICDs at baseline was significantly higher in DIGPD than in PPMI, as well as their lifetime prevalence. Both differences might be explained by the fact that PD subjects are de novo and drug-naïve at baseline in PPMI whereas they are not in DIGPD. Other phenotypes (anxiety, depression, and REM sleep disorders) were not statistically compared due to the different scales used.

Concerning genetic data, we excluded 1 genetic variant for being a variable number of tandem repeat polymorphism. Furthermore, we excluded 18 SNPs for having too low imputation quality scores. Finally, 31 SNPs were included in our analyses (Table A.1).
### Table 2.1: Baseline characteristics. For continuous variables, mean ± standard deviation is reported. For binary variables, the count for both categories is reported as well as the proportion of the first category. Statistical differences were assessed using independent t tests for continuous variables and chi-squared tests for categorical variables.

2.3.2 Predictive performance

Table 2.2 presents the predictive performance for the four main models: logistic regression using the baseline visit, the most recent visit, and the mean over all the past visits, and the recurrent neural network. The logistic regression using the baseline visit had the lowest scores on both cohorts (ROC AUC = 0.75 and AP = 0.44 in PPMI, ROC AUC = 0.67 and AP = 0.43 in DIGPD). By contrast, the recurrent neural network yielded the highest scores in PPMI (ROC AUC = 0.85, AP = 0.61), while the logistic regression using the most recent visit yielded the highest scores in DIGPD (ROC AUC = 0.802, AP = 0.64). Figure 2.3 and Figure 2.4 show the ROC and precision-recall curves for the four main models in PPMI and in DIGPD respectively. The recurrent neural network models had sensitivities of 61% and 70% and specificities of 90% and 82% in PPMI and DIGPD respectively, at the default threshold (probability > 0.5).

</table>

Table 2.2: Results of the four main models. Predictive performance for the four main models on both cohorts are reported. 95% confidence intervals were estimated using 2000 bootstrap samples. DIGPD: Drug Interaction With Genes in Parkinson’s Disease; PPMI: Parkinson’s Progression Markers Initiative; ROC AUC: area under the receiver operating characteristic curve.
All four models were statistically better than random guess \((p < 0.001)\). Logistic regression using only the baseline visit was statistically worse than at least two other models in both cohorts (Figure 2.5). The three other models were not statistically different from each other in both cohorts.

Although AP scores for the three best models were higher in DIGPD than in PPMI, the prevalence of ICDs, computed over all the (patient, visit) pairs, was twice higher in DIGPD than in PPMI (27\% in DIGPD, 14\% in PPMI). As AP scores of random guess are equal to the prevalence of the positive class, the differences between AP scores in both cohorts should be interpreted with much caution.

The other machine learning algorithms (support vector machines with linear and RBF kernels, random forest, and gradient tree boosting) and other reduction approaches (giving positive weights to all the past visits, but higher weights to more recent visits) yielded comparable results (Table A.3 and Table A.4).

To evaluate the impact of the splitting of PPMI into training and test sets on the predictive performance, we repeated the cross-validation procedure 10 times and also evaluated the 10 models on DIGPD. All iterations yielded comparable results (Table A.5 and Table A.6).

### 2.3.3 Contribution of the different features

Since the genetic factors of ICDs in PD are mostly unknown and genotyping data is not usually collected in clinical routine, we investigated the predictive performance of the same algorithms without the genetic variants as input, in order to assess their added value in the models. Table 2.3 presents the ROC AUC of the models with and without genetic variants and their statistical comparison. Only one comparison was statistically different: the logistic regression model using the most recent visit had a higher ROC AUC with genetic variants than without genetic variants (ROC AUC = 0.80 with genetic variants, ROC AUC = 0.79 without genetic variants, \(p < 0.001\)). The genetic variants did not seem to be major contributors to the decision function of the logistic regression models.

Table 2.4 presents the coefficients of the three logistic regression models without genetic variants as input (see Table A.2 for the coefficients of the three logistic regression models with genetic variants as input). As the logistic regression model using the baseline visit performed significantly worse, and the variables for PD medication were all null (PD patients in PPMI are de novo drug-naive at baseline, and the medical history of PD patients in DIGPD was not available before their baseline visit), we only interpreted the other two models. The following features had positive coefficients: sex, past ICDs, depression, REM sleep, motor exam, being on other PD medication than levodopa and dopamine agonists, and maximum dose and cumulative duration of dopamine agonists. On the other hand, the following features had negative coefficients:
Figure 2.3: ROC and Precision-recall curves on PPMI. The ROC and precision-recall curves were computed for the four models, with 95% confidence intervals behind estimated using 2000 bootstrapping samples: (A) logistic regression using the baseline visit; (B) logistic regression using the most recent visit; (C) logistic regression using the mean over the past visits; (D) recurrent neural networks using all the past visits.
Figure 2.4: ROC and Precision-recall curves on DIGPD. The ROC and precision-recall curves were computed for the four models, with 95% confidence intervals behind estimated using 2000 bootstrapping samples: (A) logistic regression using the baseline visit; (B) logistic regression using the most recent visit; (C) logistic regression using the mean over the past visits; (D) recurrent neural networks using all the past visits.
2.3. Results

Figure 2.5: Statistical comparison of ROC AUC for the four main models. 95% confidence intervals were computed using 2000 bootstrap samples. P-values were computed using the DeLong test. P-values below the 0.05 threshold after adjustment for multiple comparison using Bonferroni correction are highlighted with at least one asterisk: $p \leq 0.05$ (*), $p \leq 0.01$ (**), $p \leq 0.001$ (***).

CI: confidence interval; DIGPD: Drug Interaction With Genes in Parkinson’s Disease; PPMI: Parkinson’s Progression Markers Initiative; ROC AUC: area under the receiver operating characteristic curve.

Table 2.4: Coefficients of the three logistic regression models without genetic variants as input.
age, anxiety, being on levodopa, and mean daily and total dose of dopamine agonists. The features corresponding to being on dopamine agonists and time to prediction had coefficients close to zero. The variables with the largest absolute values were past ICDs, and total dose and cumulative duration of dopamine agonists.

2.4 Discussion

To the best of our knowledge, this study is the first one evaluating the predictability of ICDs in PD in an unbiased manner using two longitudinal cohorts, including one independent replication cohort.

Two previous studies reported ROC AUC for a prediction task of ICDs in PD (Erga et al., 2018; Kraemmer et al., 2016). Kraemmer and colleagues reported ROC AUC of 0.65 (95% CI 0.58-0.73) with clinical variables only and of 0.76 (95% CI 0.70-0.83) with clinical and genetic variables, while Erga and colleagues reported ROC AUC of 0.68 (95% CI 0.59-0.78) with clinical features only and of 0.70 (95% CI 0.61-0.79) with clinical and genetic features. However, the methods and prediction tasks were different. Erga and colleagues performed a cross-sectional analysis of 119 PD patients from the Norwegian ParkWest study, while Kraemmer and colleagues performed a longitudinal analysis of 276 PD patients from PPMI. In their studies, each patient corresponds to a unique observation, leading to much lower sample sizes. Moreover, both studies did not use cross-validation and did not have a replication cohort, which might lead to overly optimistic reported results (Koul et al., 2018). By contrast, our study uses cross-validation on the training cohort (PPMI) and has a replication cohort (DIGPD), with comparable results in both cohorts. Moreover, both cohorts have different characteristics (de novo drug-naive patients in PPMI, already-treated patients in DIGPD) and some variables (anxiety, depression, REM sleep) were not measured with the same instruments, suggesting good generalizability of the models in different settings. We also detail our methodology and provide the coefficients of the logistic regression models, so that others can investigate the predictive performance of our models in their cohorts.

The logistic regression coefficients were overall consistent with the literature. For the socio-demographic variables, sex and age have respectively a positive and negative coefficients, in accordance with a younger age and a male sex previously associated with ICDs in PD (Weintraub and Claassen, 2017). Depression, REM sleep and motor exam scores also had positive coefficients, consistent with their positive association (Grall-Bronnec et al., 2018). Anxiety scores had negative coefficients although previously reported to be positively associated with ICD. The maximum dose and cumulative duration of dopamine agonists had positive coefficients, confirming the important role of the dose and the duration of dopamine agonist therapy in the risk to develop ICDs in PD (Corvol et al., 2018). Interestingly, the types of PD medication sparsely contributed to the decision function of the models, with very small coefficients. The mean daily and
2.4. Discussion

Total doses of dopamine agonists had negative coefficients, although these coefficients were almost null for the mean daily dose. These derived features have rarely been investigated altogether, making the comparison with the literature difficult. It should be noted that the coefficients are estimated altogether and that the logistic regression models were regularized, so interpretation should be performed with caution.

Although the predictive performance of the models can be considered acceptable, the use of such models in clinical practice would deserve improving their accuracy. We used features that have been associated with ICDs in PD as input of our models, but there are probably more unknown risk factors to be discovered. In addition, as a class of psychiatric disorders, ICDs are particularly complex, with qualitative environmental factors that might play important roles, are difficult to measure, and are not captured by clinical scales used in PD. Assessment of ICDs may also be noisy (e.g. patients hiding or not aware of their behavior), and thus ICDs are probably less predictable in practice than other comorbidities in PD, such as dementia (Liu et al., 2017). Finally, little is known about the genetic factors of ICDs in PD. In absence of genome-wide association study and genetic risk scores for ICDs in PD, we used associated genetic variants from candidate gene analyses (Cormier-Dequaire et al., 2018; Erga et al., 2018; Kraemmer et al., 2016). As variation in complex traits is caused by numerous genetic variants, such analyses have important limitations and many association studies could not be replicated, particularly in psychiatric conditions like schizophrenia (Johnson et al., 2017). More studies, in particular genome-wide association studies, are needed to better understand the genetic landscape of ICDs in PD.

We used ROC AUC as the main metric to evaluate the models, and recurrent neural network models did not have much added value over logistic regression models for this metric. ROC AUC is the area under the ROC curve, plotting the sensitivity against the specificity, and summarizes how much sensitivity and specificity change for different thresholds. However, in practice, a single threshold is generally used. Using the default threshold (probability > 0.5) yielded higher balanced accuracy (mean of sensitivity and specificity) scores in the replication cohort for the recurrent neural network model than the logistic regression models, whereas this was not observed in the training cohort. This might suggest better generalizability of the recurrent neural network model than the logistic regression models when using a single threshold.

Being able to predict ICDs is of critical importance due to their potential medical, financial, and/or legal medical complications. Identifying patients at high risk to develop ICDs at the next visit may lead to changes in the dopaminergic treatment strategy (e.g. decrease the dose of dopamine agonists and increase levodopa) and/or recommend a closer monitoring of behavioral changes by the caregiver. The efficacy of such preventive strategies based on a predictive model remains however to be evaluated. In this perspective, the model may be adapted depending on the relative importance for identifying positives (patients who will develop ICDs) or negatives (patients who will not
develop ICDs). The balanced accuracy scores were equal to 76% for the recurrent neural network models in both cohorts, but the sensitivities (61% vs 70%) and specificities (90% vs 82%) differed, which might be explained by the different prevalences in both cohorts. Using the default threshold (probability > 0.5) made the models more specific than sensitive, which might be a limitation if finding the positives is more important than the negatives. On the other hand, models being more specific than sensitive might be more relevant if the main objective is to propose treatment changes only to patients who are really at risk, and avoid unnecessary modifications in more patients. The threshold can still be adjusted depending on the main objective. Prospective studies are required to validate the models and allow their relevance in clinical routine.

Our study has several limitations. First, the sample sizes are relatively small, in particular on the test set of PPMI due to the use of cross-validation, leading to large confidence intervals. Second, each observation is a (subject, visit) pair and thus the observations are not independent (the intra-subject observations are not independent, but the inter-subject observations are independent), which could lead to underestimating p-values when assessing the statistical difference between ROC AUC. Third, in absence of genome-wide association study and genetic risk scores for ICDs in PD, we used associated genetic variants from candidate gene analyses. Genetic risk scores are more robust estimators of the genetic liability of a phenotype and should be preferred when available (Wray et al., 2007).

In conclusion, our study shows that ICDs in PD can be predicted with a relatively good accuracy. The developed models were unbiasedly evaluated in two research cohorts, with comparable results. Our study highlights the utility of machine learning to automatically extract information from data and its potential to improve patient care.
Chapter 3

Exploratory analysis of the genetics of impulse control disorders in Parkinson’s disease using genetic risk scores

This chapter has been submitted to the Parkinsonism and Related Disorders journal as:

Johann Faouzi, Baptiste Couvy-Duchesne, Samir Bekadar, Olivier Colliot and Jean-Christophe Corvol. “Exploratory analysis of the genetics of impulse control disorders in Parkinson’s disease using genetic risk scores”.

Abstract

Objective  To study the association between impulse control disorders (ICDs) in Parkinson’s disease (PD) and genetic risk scores (GRS) for 40 known or putative risk factors (e.g. depression, personality traits).

Background  In absence of published genome-wide association studies (GWAS), little is known about the genetics of ICDs in PD. GRS of related phenotypes, for which large GWAS are available, may help shed light on the genetic contributors of ICDs in PD.

Methods  We searched for GWAS on European ancestry populations with summary statistics publicly available for a broad range of phenotypes, including other psychiatric disorders, personality traits, and simple phenotypes. We separately tested their predictive ability in two of the largest PD cohorts with clinical and genetic available: the Parkinson’s Progression Markers Initiative database (N = 368, 33% female, age range = [33 - 84]) and the Drug Interaction With Genes in Parkinson’s Disease study (N=373, 40% female, age range = [29 - 85]).
Results  We considered 40 known or putative risk factors for ICDs in PD for which large GWAS had been published. After Bonferroni correction for multiple comparisons, no GRS or the combination of the 40 GRS were significantly associated with ICDs from the analyses in each cohort separately and from the meta-analysis.

Conclusion  Albeit unsuccessful, our approach will gain power in the coming years with increasing availability of genotypes in clinical cohorts of PD, but also from future increase in GWAS sample sizes of the phenotypes we considered. Our approach may be applied to other complex disorders, for which GWAS are not available or limited.

3.1 Introduction

Although the cardinal symptoms of Parkinson’s disease (PD) are motor, many non-motor symptoms frequently occur during the course of the disease, including psychiatric comorbidities. Impulse control disorders (ICDs), a class of psychiatric disorders characterized by impulsivity, are common in PD, with half of PD cases expected to experience them within 5 years of the disease onset (Corvol et al., 2018). The four most common ICDs in PD are pathological gambling, compulsive eating, hypersexuality, and compulsive eating disorder. ICDs are associated with reduced quality of life, strained interpersonal relationships, increased caregiver burden, and require prompt management (Weintraub and Claassen, 2017).

Numerous factors have been associated with ICDs in PD, including socio-demographic, clinical and genetic variables (Grall-Bronnec et al., 2018). Associations from candidate gene analyses between ICDs and several genetic variants have been reported in the following genes: ANKK1 (Hoenicka et al., 2015), DAT1 (Cormier-Dequaire et al., 2018), DRD1 (Erga et al., 2018; Zainal Abidin et al., 2015), DRD2 (Kraemmer et al., 2016; Zainal Abidin et al., 2015), DRD3 (Castro-Martínez et al., 2018; Krishnamoorthy et al., 2016; Lee et al., 2009), GRIN2B (Lee et al., 2009; Zainal Abidin et al., 2015), HTR2A (Kraemmer et al., 2016; Lee et al., 2012), OPRK1 (Cormier-Dequaire et al., 2018; Kraemmer et al., 2016), OPRM1 (Cormier-Dequaire et al., 2018), and SLC22A1 (Re-denek et al., 2019). Several studies also reported no consistent associations with variants from some of the same genes (Cormier-Dequaire et al., 2018; Vallelunga et al., 2012), highlighting the variability and the lack of replication of the reported associations.

Variation in complex traits is caused by numerous genetic variants. Each genetic variant usually provides limited information because the relative causal risk of each variant is small (Wray et al., 2007). On the other hand, the combined risk of numerous low-risk variants can explain a significant proportion of the genetic variance. Genetic risk scores (GRS), obtained from genome-wide association studies (GWAS), linearly summarize the contribution of these numerous variants into a single score. Using such GRS allows for studying traits not collected in the PD cohorts or diseases that would be too rare to allow direct evaluation of the comorbidities.
ICDs in PD have been rarely studied using GRS. Only one study looked for associations between GRS and ICDs in PD (Ihle et al., 2020). In this study, authors computed a GRS of PD using 90 SNPs reaching genome-wide significance in a meta-analysis of 17 GWAS (Nalls et al., 2019) and did not find an association between this GRS and ICDs in PD. Their power was limited due to the small sample size. Furthermore, the GRS may only capture part of the genetic risk factors and would benefit from larger GWAS (Dudbridge, 2013). ICDs are not associated with PD itself (de la Riva et al., 2014), and may be associated with personality traits or psychiatric endophenotypes, which has been little studied.

Our main objective was to evaluate the predictive accuracy of a broad range of GRS in order to shed light on the genetic determinants of ICDs in PD. We were particularly interested in GRS for other psychiatric disorders, but also personality traits, including impulsivity, some of which have been associated with ICDs in PD (Callesen et al., 2014; Sáez-Francàs et al., 2016; Voon et al., 2011).

3.2 Materials and methods

3.2.1 Populations

We used data from two research cohorts: the Parkinson’s Progression Markers Initiative (PPMI) database and the Drug Interaction With Genes in Parkinson’s Disease (DIGPD) study.

PPMI (https://www.ppmi-info.org) is a multicenter observational clinical study using advanced imaging, biologic sampling and clinical and behavioral assessments to identify biomarkers of PD progression. Data was gathered during face-to-face visits every 6–12 months. PD subjects were de-novo and drug-naïve at baseline. We downloaded the clinical and genetic data from the PPMI database (https://www.ppmi-info.org/data) on the 17th of October, 2019.

DIGPD is a French multicenter longitudinal cohort with annual follow-up of PD patients (Corvol et al., 2018). Eligible criteria consist in recent PD diagnosis (UK Parkinson’s Disease Society Brain Bank criteria) with disease duration less than 5 years at recruitment. Data was gathered during face-to-face visits every 12 months following standard procedures.

Both studies were conducted according to good clinical practice, obtained approval from local ethic committees and regulatory authorities, and all patients provided informed consent prior to inclusion.

3.2.2 Participants

Inclusion criteria in our analyses included having: (i) a PD diagnosis, (ii) at least two visits measuring ICDs, (iii) clinical and genetic data available, and (iv) a European
genetic ancestry. We identified 378 subjects in PPMI and 382 subjects in DIGPD matching the first three criteria.

ICDs were assessed at each visit using the Questionnaire for Impulsive-Compulsive Disorders in Parkinson’s Disease - Rating Scale (Weintraub et al., 2012) in PPMI, and through semi-structured interviews by a movement disorders specialist in DIGPD. The ICD phenotype was defined as the lifetime presence of ICDs.

3.2.3 Genetic ancestry

To date, most GWAS have been conducted in populations of European ancestry, which limits the use of GWAS-derived GRS in non-European ancestry populations (Wang et al., 2020), and their transferability to other populations depends on many factors such as linkage disequilibrium, allele frequencies, and genetic architecture. Directly computing GRS in another ancestry group that the one from the corresponding GWAS can lead to biased GRS (Martin et al., 2017).

To estimate the genetic ancestry of the PD subjects in PPMI and DIGPD, we used data from the 1000 genomes (1000G) project to learn a low-dimensional representation of the genetic data, which captures the main dimension of ancestry. Using the 50,842 common raw SNPs between 1000G, PPMI and DIGPD, we applied the Uniform Manifold Approximation Projection (McInnes et al., 2018) (UMAP) algorithm on the 1000G data to learn a low-dimensional space of the raw SNPs. Finally, we projected the PPMI and DIGPD subjects onto the main principal components to identify in which clusters they were the closest to. Subjects projected on another cluster than the European cluster were excluded.

3.2.4 Genotyping and quality control

Genotype data was acquired using NeuroX (Nalls et al., 2015) arrays in PPMI (267,607 variants measured), and Illumina Multi-Ethnic Genotyping Arrays in DIGPD (1,779,819 variants). We excluded variants with missing rates greater than 2% and variants deviating from Hardy-Weinberg equilibrium ($p < 10^{-8}$). We excluded related individuals (third-degree family relationships), individuals with mismatching between reported sex and genetically determined sex, and individuals with outlying heterozygosity ($\pm 3$ standard deviation). We then imputed missing SNPs using the Michigan Imputation Server (Das et al., 2016) for PPMI and the Sanger Imputation Server (McCarthy et al., 2016) for DIGPD, using the reference panel of the Haplotype Reference Consortium (release 1.1) (McCarthy et al., 2016).

For GRS calculation, we selected SNPs that were (i) biallelic, (ii) frequent enough (minor allele frequency > 1%), and (iii) imputed with sufficient accuracy (R2 > 0.8 for PPMI, INFO Score > 0.9 for DIGPD).
3.2.5 Phenotypes and genome-wide association studies

Phenotypes of interest included known or putative factors associated with ICDs in PD, such as anxiety, depression, personality traits including impulsivity, eating and sleep disorders. We were also interested in more general phenotypes such as body height, body mass index (BMI), intelligence, and number of years of education, more because of the sample size of the corresponding GWAS rather than their prior association with ICDs in PD. In particular, body height and body mass index are phenotypes that are easy to collect with precision, and for which very large GWAS are available and the corresponding GRS explain a large part of the variance. These phenotypes are also usually collected in research cohorts, allowing for comparing the GRS with the true phenotypes, and thus validating our computation of the GRS.

We used the NHGRI-EBI GWAS Catalog (Buniello et al., 2019) to select the largest GWAS to date on samples of European ancestry. When summary statistics from several GWAS were available for a given phenotype, we only included the largest study.

3.2.6 Computation of genetic risk scores

When summary statistics were fully available, we estimated the coefficients of the GRS using the SBLUP (Robinson et al., 2017) algorithm implemented in the GCTA (Yang et al., 2011) software. SBLUP directly estimates GRS coefficients from summary statistics, using a reference sample to estimate the linkage disequilibrium between SNPs. When summary statistics were not available in full, we computed small GRS by performing clumping to select the most significant, low correlated variants, and directly using the coefficients provided in the summary statistics. Clumping and GRS computation were performed using the PLINK (Chang et al., 2015) software.

3.2.7 Statistical analyses

We estimated the association between the binary ICD phenotype and GRS using logistic regression, while correcting for age, sex, genetic ancestry (first four components), and the number of visits. We added the correction for the number of visits to reflect the fact that lifetime phenotype may be more likely as the number of visits increases. We performed the analyses in each cohort independently as the contributions of all the SNPs were estimated altogether, and the number of SNPs was much lower in PPMI than in DIGPD. We applied per-sample Bonferroni correction for multiple comparisons. We also investigated the association of the combination of the 40 GRS with the likelihood-ratio test.

As the sample sizes were relatively small in both cohorts, we also performed a meta-analysis to estimate the combined effects of each GRS separately and combined altogether using fixed effects models with the inverse-variance weighting method.
Logistic regressions were performed using the `statsmodels` (Seabold and Perktold, 2010) Python package. Meta-analyses were performed using the `meta` (Balduzzi et al., 2019) R package. Processing of the different text-like files was performed using the `pandas` (McKinney, 2010) and `NumPy` (Harris et al., 2020a) packages.

### 3.3 Results

#### 3.3.1 Participants and genetic variants

Out of the 378 PPMI subjects and 382 DIGPD subjects who matched the first three inclusion criteria, we excluded 10 subjects from PPMI and 9 subjects from DIGPD for being projected too far from the European cluster (Figure 3.1). Thus, we included 368 subjects from PPMI and 373 subjects from DIGPD.

Out of the 39,235,157 genetic variants of the Haplotype Reference Consortium reference panel, 601,370 SNPs in PPMI and 6,294,320 SNPs in DIGPD matched the inclusion criteria. The high discrepancy in the numbers is due to the genotyping arrays: the NeuroX array is known to have a low coverage of the genome (Nalls et al., 2015).

#### 3.3.2 Genome-wide association studies

We identified 40 GWAS that matched the inclusion criteria. Table 3.1 presents the characteristics of these studies, including the phenotype of interest, the number of SNPs, the heritability estimated from these SNPs, and the number of common SNPs between the GWAS and PPMI and DIGPD. The included phenotypes consisted of other psychiatric disorders (anxiety, depression, obsessive compulsive, and attention-deficit hyperactivity disorders (ADHD), anorexia nervosa), personality traits (impulsivity, agreeableness, conscientiousness, extraversion, openness), risk taking behaviors (automobile speeding, alcohol consumption, smoking status, sexual activity), and simple traits (body height, body mass index, intelligence, education).

Two groups of GWAS included genetic data from 23andMe\(^1\), and only the top 10,000 SNPs were made publicly available. We requested access to the whole summary statistics from 23andMe with no success.

#### 3.3.3 Association analyses

Table 3.2 presents the unadjusted p-values for the 40 GRS from the analyses on each cohort separately and from the meta-analysis. For the analysis in each cohort separately, among the 2 sets of 40 unadjusted p-values (correction is per-sample), only one was smaller than 0.05 (nominal significance), corresponding to the GRS of body mass index in PPMI (p = 0.0079). The association did not survive after Bonferroni correction.

\(^1\)www.23andme.com
Figure 3.1: Genetic ancestry estimation. (A) A two-dimensional representation of the raw genetic data was learned on 1000G, which consists of 5 super populations. The PPMI (B) and DIGPD (C) subjects were projected on this space to estimate their genetic ancestry, and excluded if their projection was too far from the European cluster. Excluded subjects are highlighted with a black circle.

Table 3.1: Characteristics of the genome-wide association studies. DIGPD: Drug Interaction With Genes in Parkinson’s Disease; PPMI: Parkinson’s Progression Markers Initiative; SE: standard error; SNP: Single nucleotide polymorphism.
Table 3.2: Results of the association analyses. Unadjusted p-values are reported for both cohorts separately and for the meta-analysis. DIGPD: Drug Interaction With Genes in Parkinson’s Disease; OR: Odds ratio; PPMI: Parkinson’s Progression Markers Initiative.
In the meta-analysis, among the 40 unadjusted $p$-values, only one was smaller than 0.05, corresponding to the GRS lack of premeditation ($p = 0.0107$). The association did not survive after Bonferroni correction.

The combination of the 40 GRS altogether was not associated with ICDs, both from the analyses in each cohort independently ($p = 0.0969$ in PPMI, $p = 0.5166$ in DIGPD) and from the meta-analysis ($p = 0.0764$).

In order to validate our GRS calculation, we assessed the quality of the GRS of body mass index by using a linear regression model with correction for age, sex and genetic ancestry. BMI was available in both cohorts, and is well studied in genetics, leading to robust GRS-based prediction (Dudbridge, 2013). In particular, the corresponding GWAS has a very large sample size ($N = 806,834$), making the estimation of each SNP contribution more robust. In both cohorts, BMI GRS were strongly associated with the measured BMI ($p = 0.000058$ in PPMI, $p = 0.000038$ in DIGPD) and the Pearson correlation coefficients were positive and high ($r = 0.21$ in PPMI, $r = 0.19$ in DIGPD). These results gave us confidence in our methodology and in the quality of the computed GRS.

### 3.4 Discussion

To our knowledge, this is the first study investigating the association between ICDs in PD and genetic risk scores for a broad range of phenotypes, including phenotypes that have been associated with ICDs in PD (Grall-Bronnec et al., 2018). Compared to a previous study that only investigated the PD GRS computed from a small number of SNPs (Ihle et al., 2020), we explored 40 phenotypes for which we computed GRS using a large number of SNPs. However, the results were mainly negative, as we did not find a single association after correction for multiple comparisons.

The main limitation of our study is the small sample size of our clinical samples, which limits discovery of small associations. The size of the GWAS is also a limitation, as GRS are imperfect predictors of the genetic liability of traits. It is known that discouraging results in many studies were due to low number of participants, and that an increase in the sample size would allow more successful results (Dudbridge, 2013). The genetic correlations between the traits for which GRS were calculated and ICDs are also unknown. Another limitation is the incomplete summary statistics made available for two groups of studies focusing on impulsivity and personality traits (collaborations with 23andMe, we contacted 23andMe but did not receive a response). For these traits, we had to compute GRS from a small number of SNPs. Computing the GRS using the whole summary statistics would likely increase the quality of these GRS.

Little is known about the genetic factors of ICDs in PD. Several studies reported associations for a few genetic variants, but they all suffer from the lack of replication, and there exists no GRS for ICDs yet. Our study could not conclude about the asso-
3.4. Discussion

Association between ICDs in PD and GRS for a broad range of phenotypes, but highlights the methodology to compute GRS and study their association with ICDs in PD for future studies, and shows how to investigate the genetic factors of a phenotype without performing a GWAS. Such study would deserve from being repeated when larger GWAS or clinical samples get available, which may boost power to detect significant associations.
Chapter 4
Combining static and dynamic data in recurrent neural networks

4.1 Introduction

Most entities that produce data at several time points have characteristics that do not depend on time. For instance, sensors provide measurements at many timestamps, but they have characteristics, such as their components, that are time-independent. Humans, as living beings, also have both types of characteristics. Their genetic data will stay identical for their whole lives, but most of their characteristics evolve over time, such as their blood pressure or blood sugar levels.

Numerous genetic and environmental factors can impact the evolution of a time-dependent characteristic. Twin studies, where subjects share identical genetic and environmental factors, have shown that many phenotypes are substantially heritable. Environmental factors, in particular qualitative ones, can be harder to measure, but their impact on many disorders have been reported. For example, smokers and coffee drinkers have a lower risk of Parkinson’s disease (Hernán et al., 2002).

Disease progression is a particular example of the evolution of a time-dependent characteristic. Many disorders are complex, with numerous comorbidities, and disease progression may greatly vary between patients. Being able to predict the future state of a patient may improve understanding of the disease and patient care.

Mathematically, the objective is to predict the future value of a dynamic target variable $y$ at time $t + \tau$, $y^{(t+\tau)}$, given input features from the present and the past. These features consist of static features $s$, that do not depend on time, and dynamic features $x$, at time $(1, \ldots, t)$, $(x^{(1)}, \ldots, x^{(t)})$. Typically, the static features correspond to genetic and socio-demographic data, while the dynamic features correspond to clinical measurements. Environmental factors can be either static or dynamic feature, depending on their nature. Without loss of generality, the target variable can be included in the dynamic input features if its past and present values are relevant to predict its future
value. This machine learning task has the following mathematical formulation

$$\hat{y}^{(t+\tau)} = f\left(s, x^{(1)}, \ldots, x^{(t)}; \theta\right)$$

where $f$ is the function predicting $\hat{y}^{(t+\tau)}$ given the static features $s$ and input dynamic features $(x^{(1)}, \ldots, x^{(t)})$, and $\theta$ are the parameters of function $f$. The function $f$ determines which information is extracted from the static and input dynamic features, independently but also dependently on each other. Different functions $f$ allow for different modelling of the interaction between the static and input dynamic features. We restrict the choice of $f$ to the class of recurrent neural networks (RNNs).

Recurrent neural networks are a class of neural networks dedicated to sequential data. The main part of a recurrent neural network is a RNN unit that takes as input a sequence of dynamic features and outputs a vector, corresponding to the information extracted from the dynamic features by this unit. However, a target dynamic feature is usually impacted not only by other dynamic features, but also by static features. Adding static features in recurrent neural networks raises the question of their integration with dynamic features.

4.2 Related work

The starting point is a recurrent neural network with no static data as illustrated in Figure 4.1. We consider a simple architecture with three layers:

- the input layer, consisting of the dynamic features;
- the hidden layer, consisting of the features extracted by the Gated Recurrent Unit from the dynamic features; and
- the output layer, consisting of the output obtained by linearly combining the hidden layer with a Fully Connected function.

A dummy way of integrating static features is to simply remove them, and we refer to this approach as static=none.

Static and dynamic data can be considered as a particular combination of multimodal data. Several studies in the medical field integrated several sources of data to improve the prediction of a phenotype. The modalities used are often imaging data, such as T1-weighted magnetic resonance imaging (T1-MRI), T2-MRI and Fluid-attenuated inversion recovery (FLAIR), and genetic data. Ge et al. (2018) integrated images from T1-MRI, T2-MRI and FLAIR modalities for glioma classification, while Punjabi et al. (2019) used T1-MRI and positron emission topography images for Alzheimer’s disease classification. Mobadersany et al. (2018) and Hao et al. (2019) integrated histopathologic images and genetic data to predict cancer outcome.
4.2. Related work

Integrating multimodal data is usually tackled with separate branches in the artificial neural networks, with the independently extracted features being concatenated near the end of the network. The corresponding architecture is illustrated in Figure 4.2, in the particular case where the raw genetic data are used. We refer to this approach as static=after. One limitation of this approach is the late interaction between the static and dynamic features, as each branch extracts information from the input data independently. If the static and dynamic features are correlated, we may want to provide both kinds of features to the GRU.

Most studies focusing on the integration of static and dynamic data have been identified in the literature of churn prediction. In these studies, the objective was to predict which customers will unsubscribe to a service or which users will not log at least once into a platform in the near future. The dynamic features consisted of the activity of the users, while the static features included socio-demographic information about the users. Besides the two aforementioned methods, two other approaches have been proposed. The first one consists in treating static data as dynamic data (Leontjeva and Kuzovkin, 2016; Rahman et al., 2020). The static features are repeated at each time point by being concatenated to the vector of dynamic features. This approach is illustrated in Figure 4.3 and is referred to as static=dynamic. One obvious limitation of this method is that static data is treated as dynamic data, which may be suboptimal because of the different nature of these features.

The other approach consists in initializing the parameters of the GRU with the static features (Kristensen and Burelli, 2019). A Fully Connected function is used to
Chapter 4. Combining static and dynamic data in recurrent neural networks

Figure 4.2: Recurrent neural network with static data on its own branch. Information is independently extracted from the dynamical and static features, in their own branches. The extracted information is then concatenated before the fully connected layer. In this example, the raw static features are directly used.

Figure 4.3: Recurrent neural network with static data treated as dynamic data. The static features are repeated at each time point and concatenated to the dynamic features.
4.3 Proposed approach

We propose another approach to integrate static data in recurrent neural networks. Similarly to the static=dynamic method, this approach introduces the static features linearly combine the static features into a vector with appropriate size. This approach is illustrated in Figure 4.4 and is referred to as static=init. One limitation of this approach is that the information from the static features is added in the initialisation of the GRU and may vanish after a few time points. Otherwise, having to keep the information from the static features may prevent it from extracting other useful information from the dynamic features.

To summarize the four identified approaches, static features can be:

- removed (static=none),
- put after the GRU (static=after),
- treated as dynamic features (static=dynamic), or
- put at the same level as the GRU (static=init).

These approaches allow for modelling different interactions between the static and dynamic features.

4.3 Proposed approach

We propose another approach to integrate static data in recurrent neural networks. Similarly to the static=dynamic method, this approach introduces the static features
before the GRU. However, instead of putting the static features at the same level as the
dynamic ones, they are put before and used to modify them.

More specifically, the new dynamic feature $\tilde{x}_i$ is the product between the original
dynamic feature $x_i$ and a linear combination of the static features:

$$\tilde{x}_i = x_i \times \left( b + \sum_{k=1}^{p} s_k \right)$$

and the sequence of new dynamic features $(\tilde{x}^{(1)}, \ldots, \tilde{x}^{(t)})$ is used as input of the GRU.
This approach is illustrated in Figure 4.5 and is referred to as static=before. An
element-wise multiplication with a linear combination of the input boils down to adding
a Fully Connected function followed by an element-wise product between the static and
dynamic features.

This method models a high level of interaction between the static and dynamic
features. Similarly to the static=dynamic and static=init approaches, the GRU is
provided the static features and can thus extract information from both the dynamic and static features. Instead of treating static features as dynamic ones, which does not take into account the difference in modalities, or initializing the GRU with the static features, which may dilute the information of the static features over time, this approach models a time-independent interaction between the static and dynamic features.

4.4 Experiments

We investigated the five approaches to integrate static data in recurrent neural networks to predict impulse control disorders in Parkinson’s disease. The objective was identical to the one presented in chapter 2, that is predicting the presence or absence of ICDs (binary variable) at the next visit for a given subject given all the current information on this subject:

$$\hat{y}^{(t+1)} = f(s, x^{(1)}, \ldots, x^{(t)}; \theta)$$

In addition to the clinical, socio-demographic and SNP data used, we integrated genetic ancestry and genetic risk scores as input of the models. These new features were naturally considered as static data.

We use genetic data from the 1000 Genomes project\(^1\) to learn a low-dimensional representation of high-dimensional raw genetic data. We then projected the subjects from the PPMI and DIGPD cohorts onto this low-dimensional space and removed the subjects not being projected on the European cluster. Genetic ancestry was derived as the first ten components of this low-dimensional space and added as static features.

Genetic risk score were computed using only the common SNPs between PPMI and DIGPD. Out of the 40 GRS presented in chapter 3, 13 were removed because the provided summary statistics were too small. The corresponding genome-wide association studies were performed using data from 23andMe\(^2\), and only the top 10k variants were made available. Table 4.1 presents the characteristics of the 27 GWAS and the corresponding GRS were added as input to the models.

The cross-validation was similar to the one presented in chapter 2 and is illustrated in Figure 4.6. We employed a nested cross-validation on PPMI that was used as the discovery cohort, and also evaluated the models on DIGPD that was used as the replication cohort, with 10 repetitions of the whole process. The 10 models were used to compute the mean and standard deviation for the area under the ROC curve and the average precision.

Results are presented in Table 4.2. The five approaches yielded comparable results, with ROC AUC around 0.83 and 0.79 on PPMI and DIGPD respectively, and average precision around 0.53 and 0.61 on PPMI and DIGPD respectively. The static=dynamic method had the lowest scores on both cohorts, suggesting that this approach may be

Columns are: study, phenotype, number of subjects in the study, variance explained by the SNPs, and the number of common SNPs between the study, ADNI, PPMI and DIGPD.
4.5 Conclusion

Figure 4.6: Cross-validation procedure. PPMI was used as the discovery cohort, on which we performed a nested cross-validation to estimate the performance. This process was repeated 10 times, and the corresponding 10 models were applied on DIGPD, used as the replication cohort.

Table 4.2: Predictive performance of the five approaches. Mean (standard deviation) over the 10 repetitions are reported.

Suboptimal. Overall, the different approaches to integrate static data in recurrent neural networks had little to no impact on the predictive performance with these data.

4.5 Conclusion

Combining static and dynamic data is an underexplored topic. We reviewed the literature on integrating static data in recurrent neural networks and identified four approaches. We proposed a new method modelling a high-level interaction between the static and dynamic features, consisting in multiplying each dynamic feature by a linear combination of the static features. We experimented the five approaches in the prediction of future impulse control disorders in Parkinson’s disease. The dynamic features consisted in clinical measurements, while the static features corresponded to genetic
and socio-demographics data. The results showed that the five approaches yielded comparable results. This use case has been underexplored from a machine learning point of view and little is known on the association between genetics and impulse control disorders in Parkinson’s disease, which could explain why changing the approach had little to no impact on the predictive performance. Future work includes applying the five approaches to another use case, where the interaction between the static and dynamic features is known to be high, and simulating data to gather more knowledge on which approach works best based on the interaction.
Conclusion and perspectives

Conclusion

We proposed several approaches to investigate the predictability of impulse control disorders in Parkinson’s disease. First, we investigated the predictability of ICDs in PD using as input a broad range of features that have been associated with ICDs. Second, we studied the association between ICDs in PD and genetic risk scores for numerous phenotypes, including other psychiatric disorders and personality traits. Third, we investigated the integration of static (time-independent) features in recurrent neural networks with an application in the prediction of ICDs in PD. We summarize here our conclusions regarding each of these studies.

In a first study, we investigated the predictability of ICDs in PD using as input a broad range of features that have been associated with ICDs (with varying degrees of confidence and replication). Our objective was to predict the presence or absence of ICDs at the next visit for a given patient. We trained several machine learning algorithms, representing a broad range of complexity and relationships, on a discovery cohort. We highlighted that this longitudinal binary classification task could be addressed with relatively good accuracy, and that only a subset of the associated factors was involved in the decisions of the simplest models. We also evaluated the models in an independent cohort and obtained comparable results.

In a second study, we investigated whether the genetic factors of many traits were associated with ICDs in PD. The genetic factors of ICDs in PD are poorly known and most studies focus on candidate genetic variants. However, complex traits are likely to be affected by numerous variants and genes. In this case, single genetic variants usually provide limited information because the relative risk of each variant is small. On the other hand, the combined risk of numerous low-risk variants can explain a significant proportion of the genetic variance. The risk of each variant is linearly combined to derive a genetic risk score. We computed genetic risk scores for a broad range of phenotypes, including other psychiatric disorders, personality traits, and simple phenotypes. We assessed the associations between these genetic risk scores and ICDs in PD and found
no association.

In a third study, we investigated the integration of static features in recurrent neural networks. We reviewed the existing literature and identified several approaches. We proposed a new approach consisting in modifying the dynamic features using a linear combination (or more generally a function) of the static features, modelling a high level of interaction between the static and dynamic features. We evaluated all the approaches in the use case of predicting the presence or absence of ICDs at the next visit for a given patient. The static features consisted of socio-demographic and genetic features. All the approaches (including removing the static features) led to very similar results, suggesting that the static features do not provide more information than the dynamic features in this use case.

**Perspectives**

A natural perspective when developing machine learning models for a medical application is the increase of sample size.

First, a larger sample size on the training cohort can improve the generalization capability of the fitted models. Learning curves in machine learning usually show that, when the sample size is relatively small, an increase in sample size leads to a significant improvement in predictive performance, but when the sample size is already large enough, a similar increase in sample size has little to no impact on the predictive performance. Learning curves, and thus the definition of low and large sample sizes, highly depend on the algorithm and the difficulty of the task.

Second, a larger sample size increases the statistical power and can allow for the discovery of associations with small effects. Both research cohorts from which we obtained data had only a few hundreds subjects, making the discovery of associations with small effects very unlikely. A larger sample size could shed a new light on the common genetic factors between ICDs in PD and other phenotypes, notably other psychiatric disorders and personality traits.

Third, we could evaluate our models in other research cohorts. We showed that the replication on an independent cohort with different characteristics was possible. Evaluating our models in other research cohorts would be a big step towards estimating their generalization capability.

Fourth, we did not evaluate our models in real-life clinical cohorts, which is an essential step to assess the generalization capability of the models and to deploy the models
in clinical routine. Clinical cohorts usually have different characteristics from research cohorts: more missing data, less clean data, more varying time gaps between consecutive visits, less standardized protocols. All these differences can negatively impact the predictive performance of models that have not been trained on data with these characteristics.

Fifth, we showed that predicting impulse control disorders at the next clinical visit can be achieved with correct accuracy, but the predictive performance of these models may still be too low to be used in clinical routine. Investigating which threshold to binarize the predicted probabilities into decisions is the most adapted in practice would be of great interest. Combining the predictions of the models and the expertise of clinicians may also improve the predictive performance.

Finally, impulse control disorders have been reported in a few other diseases treated with dopamine replacement therapy, notably restless leg syndrome. Evaluating our models in cohorts with another disease could be interesting in order to see if ICDs in PD have different characteristics than ICDs in other diseases.
A.1 Reduction approaches

Algorithms like logistic regression expect a fixed number of features as input. In order to deal with varying numbers of visits, we reduced all the previous visits into one “summary” visit using a convex combination. A convex combination is a linear combination such that the weights are all non-negative and sum to one. The weights indicate how much each visit contributes to this summary visit. A weight of 1 for the first visit means that the summary visit is simply the baseline visit, while a weight of 1 for the latest visit means that the “summary” visit is simply the most recent visit. One can also give uniform weights, so that each visit contributes equally to this “summary” visit, or higher weights to most recent visits if they are assumed to be more important than older visits.

Mathematically, if we have observations $x$ at $T$ time points:

$$(x^{(1)}, \ldots, x^{(t)}, \ldots, x^{(T)})$$

a convex combination is simply:

$$\sum_{t=1}^{T} w_t x^{(t)}$$

such that $\forall t, w_t \geq 0$ and $\sum_{t=1}^{T} w_t = 1$
Each $w_t$ is the weight of time point $t$ in this “summary” visit. The following table summarizes the different convex combinations that we investigated:

<table>
<thead>
<tr>
<th>Name</th>
<th>Weight $w_t$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Reduction 1</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \begin{cases} 1 &amp; \text{if } t = 1 \ 0 &amp; \text{otherwise} \end{cases}$</td>
</tr>
<tr>
<td>Reduction 2</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \begin{cases} 1 &amp; \text{if } t = T \ 0 &amp; \text{otherwise} \end{cases}$</td>
</tr>
<tr>
<td>Reduction 3</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{1}{T}$</td>
</tr>
<tr>
<td>Reduction 4</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{\exp(\sqrt{t})}{\sum_{l=1}^{T} \exp(\sqrt{l})}$</td>
</tr>
<tr>
<td>Reduction 5</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{\sqrt{t}}{\sum_{l=1}^{T} \sqrt{l}}$</td>
</tr>
<tr>
<td>Reduction 6</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{\exp(t)}{\sum_{l=1}^{T} \exp(l)}$</td>
</tr>
<tr>
<td>Reduction 7</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{t}{\sum_{l=1}^{T} l}$</td>
</tr>
<tr>
<td>Reduction 8</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{\exp(t^2)}{\sum_{l=1}^{T} \exp(l^2)}$</td>
</tr>
<tr>
<td>Reduction 9</td>
<td>$\forall t \in {1, \ldots, T}, w_t = \frac{t^2}{\sum_{l=1}^{T} l^2}$</td>
</tr>
</tbody>
</table>

Reduction 1 corresponds to the baseline visit, while reduction 2 corresponds to the previous visit, and reduction 3 corresponds to the mean over the past visits.
